Voltage Surges on Underground Cable Systems. In the course of the studies which have been made of high voltage transients on underground cable systems klydonographs have been installed on 16 cable systems for the purpose of obtaining operating records of transients on these systems. The highest voltage recorded was 4.6 times normal. Nearly 99 per cent of all the surges recorded were under three times normal and 92 per cent of the total were unidirectional and therefore of brief duration. As the highest surges are of the same order as the commonly specified test voltage of the cable, but last only a small fraction of a second, it is probable that they have no effect on the cable insulation.

Use of Temperature Indicators on Distribution Transformers

Experience which has been obtained from the use of temperature indicators on distribution transformers in Boston has indicated that material savings may be accomplished due to a better loading of the transformers. Some operating companies, however, feel that temperature indicators are not a satisfactory substitute for load tests but in any case it is probable that under cool weather conditions where the ambient temperature is materially below 40 deg. cent. which usually corresponds to the peak-load season in Northern cities the transformers can be safely loaded to values considerably in excess of their rating. An important reduction in transformer investment may thereby result.

PHILIP TORCHIO, *Chairman.*

Discussion

D. W. Roper: This report calls attention to some of the lightning arresters and distribution circuits in Chicago. For fear that the readers might get a wrong impression, I want to add a little to what appears in the report. The lightning-arrester records of the several types appeared to indicate that the results obtained were not quite what were expected. Further investigation of that point has brought out an interesting feature, somewhat unlooked for, in that some of these burn-outs which have been recorded and which have affected our results were due to lightning entering via the secondary circuits. The lightning arresters we have are on the primary circuits. The primary distribution, in general, occupies the top arm and the secondary ordinarily the next lower arm. Sometimes it is on the same arm with the primary circuits. As the lightning potentials which appear on the line are in proportion to the height from the ground, it is seen that the secondary circuits have been getting almost the same lightning effects as the primary.

We have examined a few transformers—not very many—but as nearly as we can determine from the few which we have examined, something like one-third of our transformer burn-outs have been due to lightning which entered the secondary winding. We can hardly blame the lightning arresters which are connected to the primary circuits if some transformers burn out due to lightning entering on the secondary circuits.

S. J. Rosch: The report under the paragraph on Underground Cables, says, "There is a pronounced drift toward the use of single-conductor cables and three-conductor metal-sheathed unbolted cables." I believe it would be highly advisable in view of its importance, to include in this report some figures indicating the quantity of the latter type of cable now in use in this country. Undoubtedly, many operating engineers in making up their 1928 budget, will naturally look to this and similar reports, for an indication of what type of cable to purchase for their three-phase circuits, whether to use three-single conductors, the regular belted three-conductor cable, or the metal-sheathed unbelted type. It would also be of value to have some figures on the probable use in the near future, of the latter type of cable.

Alfred Herz: I have one question in mind in regard to the inter-bonding or grounding of cable sheaths. We all realize that considerable longitudinal voltage makes its appearance in these sheaths, especially in a sheath surrounding a single-conductor cable. What is the practise in taking care of, or rather in avoiding detrimental effect when you bond or ground such cable sheaths?

Philip Torchio: Answering Mr. Rosch's inquiry as to what per cent of three-conductor cable is now of the metal-sheathed unbelted type, I think there is a very small amount in use at the present time but several manufacturers are ready to make it and a considerable demand for it is anticipated.

Regarding the surge voltages on underground cables as indicated in the report the maximum recorded was 4.6 times normal. Now a cable which is operated at 40 to 50 volts per mil is tested at about 165 volts per mil so that the normal 5-min. test voltage is about four times the normal operating voltage. There remains still a large margin above the test voltage before actual breakdown is reached so that a surge of 4.6 times normal especially in view of its brief duration should not give deterioration. This is in further explanation of the Committee's intent in giving that view.

Replying to Mr. Herz's question about taking care of the induced voltages and currents in the sheaths of single-conductor cables, that can be done by providing insulating joints in the sheaths and cross connecting the insulated sheath sections in such a manner that the induced voltages are counterbalanced. As an alternative the insulated sheath sections may be grounded at one end giving a voltage normally of a few volts at the other end of the section which may under short-circuit conditions reach values of the order of 100 volts.

Herman Halperin: (communicated after adjournment) In the last part of the report, there is a discussion regarding the migration of oil from oil-filled joints into cable, and it is stated that the oil "no doubt reduces or possibly eliminates voids, especially near the joints." Then, at the end of the same paragraph is the following: "The use of such oil-filled joints makes it possible that satisfactory single-conductor cables of the usual type of construction may be obtained for operation at 110-kv., 3-phase."

Up to a few years ago, joints were the limiting feature for underground cables in going to higher voltages, but with the recent development in joints, this limit has been removed. In connection with the last quotation, if the cable as it leaves the factory is not of a quality to give satisfactory operation at 110-kv., 3-phase, then, according to experience with cable made in the past year, the addition of oil-filled joints will not make the cable operate satisfactorily. Apparently, this was not the intent of the quoted statement, but one might infer it from reading the report. Operating and laboratory data indicate that the principal factors necessary to obtain satisfactory 110-kv. cable are either to improve the quality of cable insulation furnished in cables of ordinary construction, or change the cable construction, or both.

In Chicago, No. 10 transformer oil has been used for filling about 150 three-conductor, 33-kv. joints and 750 single-conductor, 75-kv. joints. There have been occasions to examine the joints and cable adjacent in connection with cable failures, and the insulation next to the joint has been usually found well impregnated, partly due to the migration of oil from the joint into the cable insulation. However, considerable deterioration has been found in the cable insulation as close as 2 ft. from the joint.

In connection with laboratory tests on 75-ft. lengths of single-conductor, 75-kv. cable and also with lengths that had been in service several months, dissection has shown that the distance the oil traveled from potheads or joints, varied from a few feet next to the sheath to a maximum of about 50 ft. along the strands of the conductor, depending on the kind of impregnating compound in the cable insulation. The penetration of the oil readily into the insulation was for only a few layers, except for the few feet of cable mmediately adjacent to the potheads or joints.

Operating experiences with underground lines and tests on cable samples have indicated great variations in the quality of insulation along the length of cable.

Apparently the effectiveness of oil in improving the quality of the insulation is practically limited to only a few feet, which is very short in comparison to the length of a section of cable between manholes that may be 400 to 700 ft. long.

W. A. Del Mar: (communicated after adjournment) The maintenance of impregnation is now recognized as an essential element of success in the operation of high-tension cables, and the report clearly calls attention to the distinction between the use of oil-filled joints with reservoirs and the hollow-core type used on the 132-kv. circuits at Chicago and New York.

Another distinction which might be made is between two variants of the former type, namely, cables in which the reservoirs are used merely to maintain the impregnation and those in which they are used to maintain a definite pressure within the cable. The former type is subject to limitations, especially where the cable is impregnated with a jelly compound, as the reservoir oil penetrates very slowly, and there is a tendency for the residual air to accumulate near the center of the section of cable. The latter type, *i. e.*, where the system is designed for pressure maintenance rather than penetration, assumes that air will be present and provides means for making it harmless. This is done subjecting the air to such pressure that it will not ionize at the existing dielectric stress.

An experimental installation of this kind has been made in Detroit, bellows reservoirs being used, which are kept under a pressure of approximately 0.4 atmosphere above normal by means of weighted lever. The desired pressure was predetermined as indicated in the discussion of my paper on *The Effect of Internal Vacua*, JOURNAL A. I. E. E., Oct. 1926, p. 1012, *i. e.*, the maximum dielectric stress in the cable was calculated and the air pressure determined at which thin air films begin to ionize at this stress. The reservoir pressure was set slightly above this point.

It is obvious that the success of this pressure system depends to some extent on the use of cable impregnating compound which is fairly soft or fluid at operating temperatures.

Protective Devices

Annual Report of Committee on Protective Devices*

To the Board of Directors:

This committee in its report last year gave a rather complete survey of the present state of the art in the field of protective devices for power systems. As many of the principal features of that report still describe the present practise in these various lines, the committee will report at this time more especially its activities during the past year.

The principal work of the committee this year has been, first, in the arranging for and the actual preparation of papers for presentation at meetings of the Institute, of which about 15 have been presented as listed in the reports of the subcommittees following, and second, in the work of standardization in connection with which during the year there were issued two reports on standards, one for lightning arresters and one for automatic stations.

The work of the committee has been carried on by subcommittees, each under the direction of its own chairman, and after the first organization meeting of the main committee, held at Chicago in October, the further meetings have been held by the subcommittees individually. The subjects covered and the chairmen in charge of the subcommittees are as follows:

Automatic Stations, W. H. Millan, Union Electric Light & Power Co., St. Louis, Mo.

Current Limiting Reactors, E. A. Hester, Duquesne Light Co., Pittsburgh, Pa.

Lightning Arresters, J. A. Johnson, Niagara Falls Power Co., Niagara Falls, N. Y.

Oil Circuit Breakers, J. M. Oliver, Alabama Power Co., Birmingham, Ala.

Protective Relays, H. P. Sleeper, Public Service Electric & Gas Co., Newark, N. J.

Reports of the individual subcommittees follow.

Subcommittee on Automatic Stations

Four papers have been arranged for by this subcommittee during the year:

Carrier-Current Selector Supervisory Equipment, by C. E. Stewart and C. F. Whitney.

Testing, Inspection, and Maintenance of Automatic Stations, by Chester Lichtenberg.

Automatic Substations, by D. W. Ellyson.

Development of Automatic Switching Equipments in United States and Europe, by A. H. de Goede.

In the matter of standardization, this subcommittee has prepared and circulated Report No. 26 on Standards for Automatic Stations. Criticism of this report is invited and it is hoped that many engineers to whom the report will be sent will respond with such suggestions as will permit adjustment of the substance of the report into a final set of standards.

In the matter of research work it has been suggested that the application of automatic control has a direct influence on the degree of service actually rendered, and that a study should be made of the subject, with a view to determining to what extent, if any, automatic control of station equipment has improved service.

Subcommittee on Current Limiting Reactors

Since there has been no marked progress in design, and since no very unusual installations have been called to the attention of the subcommittee, the subject of development will be passed with just a word. The fact that practically all new reactors now being installed are of the insulated conductor type shows that it is to be preferred over the older type with bare conductors. The superiority of insulated conductors has also been rather definitely proved by exhaustive tests. There seems to be some hesitancy on the part of operating engineers to go to the use of reactors of a higher voltage than 33,000 volts, although there are some successful installations of higher voltages, and manufacturers express their confidence in being able to produce satisfactory high-voltage equipment.

In last year's report, certain recommendations were made covering subjects to be studied this year. These were for the most part problems which have been considered by previous subcommittees and to which no solution has yet been discovered. Chief among these is the question of the value of resistance shunted reactors. It was hoped that the extended use of the klydonograph and Dufour oscillograph would shed some light on this much mooted question, but nothing conclusive has been obtained.

Another suggestion was that some work be done in an effort to reduce the variety of reactors with respect to voltage, current, and reactance values. The idea was that they might be standardized, with respect to their various characteristics, in steps in much the same way as has been done on oil circuit breakers. This was discussed at one of the Main Committee meetings and a decision handed down that this problem properly belongs to the N. E. L. A. rather than to the A. I. E. E.

Further study of possible standardization for reactors is now under way.

*Committee on Protective Devices:

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

Subcommittee on Lightning Arresters
March 24, 1927

Papers and Research. Last year's report described in considerable detail two new tools which have become available for the study of lightning and other transient electric phenomena; namely, the klydonograph and the Dufour cathode ray oscillograph. That report also suggested three items of further work to be done; namely:

1. Standardization of technique for using lightning generators for testing lightning arresters,

2. Determination of voltage time characteristics of lightning arresters including rate of discharge, and the dielectric spark lag,

3. Statistical data of operating experience on high-voltage lines.

During the past year, substantial progress has been made along these lines by the use of the two devices above mentioned. This progress is recorded in the following papers presented before the Institute during the past year:

1. *Lightning and Other Experiences with 132-Kv. Steel Tower Transmission Lines*, by M. L. Sindeband and P. Sporn, JOURNAL, Vol. XLV, No. 7, p. 641.

2. *Measurement of Transients by the Lichtenberg Figures*, by K. B. McEachron, JOURNAL, Vol. XLV, No. 10, p. 934.

3. *Lightning—A Study of Lightning Rods and Cages with Special Reference to the Protection of Oil Tanks*, by F. W. Peek, jr., JOURNAL, Vol. XLV, No. 12, p. 1246.

4. *Measurement of Surge Voltages on Transmission Lines Due to Lightning*, by Everett S. Lee and C. M. Foust, JOURNAL, Vol. XLVI, No. 2, p. 149.

5. *Transmission Line Voltage Surges*, by J. H. Cox, JOURNAL, Vol. XLVI, No. 3, p. 263.

6. *Klydonograph Surge Investigation*, by J. H. Cox, P. H. McAuley, and L. Gale Huggins, JOURNAL, Vol. XLVI, No. 5, p. 459.

Since the progress in research during the year in general is summed up in the conclusions of these papers, it seems worthwhile to restate these conclusions here in so far as they throw light on the nature and magnitude of lightning surges and the characteristics of the devices being used to investigate them.

Mr. McEachron's paper concludes as follows:

"As a result of this investigation, it can be definitely stated that the size and appearance of both positive and negative Lichtenberg figures are dependent on the wave front as well as on the crest voltage.

Throughout the range of wave fronts probably found in service, the size of the positive figure is not much changed by a change in wave front only, except at voltages close to the upper limit of potential where a decrease in the size of figure is indicated with very abrupt fronts.

The positive figures may be divided into three type forms which are partly determined by wave front and partly by the value of the crest voltage. It is possible to gain some idea of the steepness of the front from the appearance of the positive figure.

The size and appearance of the negative figures are considerably affected by changes in wave front, the steepest waves always giving the largest figures. The percentage change with a constant crest voltage applied is greatest for the lower voltages. The change seems to be great enough so that it cannot be neglected. The negative figures change in appearance with increasing steepness of wave front, but the changes are so indefinite that it is only possible to state that a particular negative figure probably represents a fast wave or a slow wave."

The paper by Lee and Foust contains field klydonograph records showing surge voltages on a transmission line as high as 1500 to 2100 kv. In one case this was a highly damped oscillatory surge predominantly negative; in another case it was a unidirectional surge with positive polarity.

Practically all figures obtained on transmission lines were of the type II class (paper by McEachron) and may be placed, therefore, within the wide range of wave fronts which vary roughly from that of a slow 60-cycle wave to a surge which comes to its maximum value in a fraction of a microsecond.

The maximum surge voltages obtained compare favorably with the laboratory results of insulator flash-over tests; the value 1800 kv. for the lightning spark-over of a 14-unit insulator string seems to be close to the upper limit of voltages actually measured on the line by means of recorders. The authors summarize this paper as follows:

"It has been shown that surge voltage recorders using the positive photographic Lichtenberg figures have given essentially the same calibration data under a variety of conditions; also that the accuracy of such an instrument is in the order of 25 per cent, with a somewhat better value possible for those measurements wherein several similar observations may be obtained.

"An extension of instrument design has been described wherein two recorders are used together, which allows the use of the positive figure as a voltage measure of all surge voltages, thus insuring greater certainty of result. A more comprehensive analysis of the figure characteristics is also possible, since both positive and negative figures are available.

"A means of connecting the surge voltage recorder to a transmission line of higher than instrument voltage has been described which has been proved in service to be simple, reliable, and easy to calibrate. Calibration data are presented to show that with such connection, reasonable accuracy may be obtained in recording voltages up to values in the order of 2000 kv. A specimen record of such voltages obtained in the field is shown.

"The records which can be obtained from surge voltage recorder instruments connected as desired along a transmission line will allow the facts regarding surge voltages on transmission lines to be determined with reasonable exactness."

Mr. Cox's paper concludes as follows with respect to lightning:

"1. Positive lightning strokes are frequent but weak. They are slow, of the order of 0.01 sec., and hence do not induce surges on transmission lines.

"2. Positive strokes, even though slow, may produce surges of importance on isolated low-voltage lines, such as communication lines.

"3. Negative lightning strokes are less frequent but more violent. They discharge in about *three microseconds* and hence produce high-voltage surges on transmission lines.

"4. The field gradient is often as high as 60 kv. per ft. and may reach 100 kv. per ft. Thus a surge of over 2000 kv. might be induced upon a line of ordinary height with sufficiently high insulation. *Eighteen hundred kv. has been recorded by the klydonograph.*

"5. The time lag of an insulator flashover is less than the time of discharge of a negative stroke and thus the impulse flashover voltage of the insulators limits the possible potential.

"6. The stroke of lightning itself is unidirectional. If an oscillatory surge due to lightning is recorded, it is a line oscillation resulting from a flashover."

The paper by Cox, McAuley, and Huggins contains the following conclusions with respect to lightning:

"1. Surge voltage due to lightning is unidirectional. The clouds which produce surges are of negative polarity, resulting in positive induced voltages and negative direct-stroke voltages.

"2. The maximum values, reached by lightning surges on transmission lines, are limited by the flashover of the insulators. It is believed that the flashover voltage of 220-kv. transmission line insulation, at the steepnesses of wave front of lightning surges, is comparable to the maximum potentials ordinarily induced by lightning.

"3. The flashover voltage of the average insulation of lines up to 140 kv. is about seven times normal for lightning impulses.

"4. Seldom more, and often less than two surges, comparable in magnitude to the insulator flashover voltage, appear at a given point of a line during a storm.

"5. The frequency of occurrence of the higher surges does not seem to be greater for low-voltage than for high-voltage lines.

"6. High-voltage surges are damped below the corona voltage in traversing a few miles of line. At low magnitudes they may travel long distances.

"7. The quantitative measurements with the klydonograph agree with the theories regarding induced voltages and the protection against these afforded by the ground wire.

* * * * * * * * * * * * *

"13. Except for lightning surges and arcing grounds, no high-voltage disturbances of particular importance to the operating engineer appear on transmission lines.

* * * * * * * * * * * * *

"18. In the investigations of the performance of lightning arresters in actual service, it was found that arresters in general give satisfactory operation, that is, they relieve all surge voltages above the standard test voltages for equipment insulation. Discharge currents up to 2500 amperes occur in practise. From these tests it is concluded that the field performances of arresters confirm predictions based on laboratory tests.

"19. Lightning arresters do not protect a line against flashovers at distant points."

It is desired to call particular attention to Fig. 12 of the paper by Lee and Foust which shows results of klydonograph calibrations reported by Messrs. Cox and Legg, Mr. McEachron, and Messrs. Lee and Foust. "These results show remarkable agreement for the work of the different observers in different laboratories, with different instruments and circuits, and give added weight and certainty to the calibrations of the Lichtenberg figures in regard to magnitude of voltage."

As for the determination of wave shape from Lichtenberg figures, the following excerpt from the paper by Messrs. Lee and Foust is significant:

"At the present time, the determination of wave shape from the Lichtenberg figure characteristics is not as definite or as certain as the determination of the magnitude from the figure size, and herein there is room for added study. Further study along these lines tending toward greater exactness in the interpretation of figure characteristics is desirable."

From the foregoing results of the researches of the several investigators, the following significant summary of present knowledge may be made:

1. Lightning strokes are unidirectional.

2. Positively charged clouds discharge in about one one-hundredth of a sec.; negatively charged, in about three microsec.

3. Surge voltages due to lightning are usually unidirectional. The clouds which produce surges are of negative polarity, resulting in positive induced voltages and negative direct-stroke voltages. Oscillatory surges are the result of flashovers and are highly damped.

4. The wave front steepness, or time required for a lightning surge to reach its crest, lies within the broad range between about one one-hundredth of a second and one microsec. The steepest waves probably reach their crest in a time of the same order as that required for the discharge of a negatively charged cloud, namely, about three microsec.

5. The maximum potential of lightning surges agrees with theory and laboratory tests and is limited by the flashover value of the line insulators.

6. Lightning arrester performance in service confirms laboratory tests.

With the foregoing facts reasonably well established, it would appear that the establishment of standards for lightning arresters and lightning arrester test apparatus and procedure may now be undertaken upon a rational scientific basis.

Standards. The progress which has been made during the past year is bringing nearer the time when rational standards for lightning arresters can be formulated. Since the lightning arrester is a device for dealing with transient voltages, the standardization of arrester characteristics and testing devices and procedure upon a rational basis demands the adoption of a *standard transient potential or lightning surge.* Such a standard transient or lightning surge should resemble as nearly as laboratory limitations will permit, the most destructive surges which natural lightning produces on transmission circuits. Sufficient evidence is now available to indicate that such natural surges reach their crest values in a time on the order of three to four microsec. It is believed that the demand of the art at the present time for the adoption of a standard transient for lightning arrester testing is sufficient to justify the adoption at this time of a tentative standard. Therefore, in the formulation of standards for lightning arresters, in which work the subcommittee is now actively engaged, it is proposed to establish a standard lightning surge for laboratory use which it is proposed to define as follows:

"The standard lightning surge shall be one which rises to its crest value in four microsec. and which does not decrease more than 2 per cent in the following 10 microsec."

For the purposes of lightning arrester standardization, it is proposed to fix the maximum value of the standard lightning surge at 100 kv. in order to limit the size of the necessary laboratory equipment.

It is felt that the accelerated progress which will result from the agreement upon a standard transient is sufficient justification for the adoption of such a standard at the present time, even though further experience may indicate that the exact form of the standard adopted may have to be changed. The Institute has a standard for cyclic voltages, namely, the sine wave. There would seem to be no reason why it should not likewise have a standard for transient voltages. Possibly more than one such standard may be required for different purposes.

Since the entire matter of standardization of test procedure for lightning arresters depends upon the adoption of a standard transient, the matter is mentioned here in order that the committee may have the benefit of open discussion of the matter in the work of formulating standards on this most difficult subject.

It is also desired to point out here that the cathode ray oscillograph is rapidly supplanting the use of sphere-gaps in determining the voltage and current characteristics of lightning arresters, and that consequently such terms as "equivalent sphere-gap," "discharge rate," and "dielectric spark lag" are rapidly being left behind, and are being replaced by actual voltage and current curves obtained with the cathode ray oscillograph. Such cathode ray oscillograms can be interpreted in terms of actual volts, amperes and times, even down to fractions of a microsecond, and consequently give far more comprehensive information regarding the performance of lightning arresters than ever was or ever could be possible from the use of sphere-gaps.

It is hoped that the standards now under preparation, in connection with which a considerable amount of research is also under way, may be sufficiently advanced for presentation sometime within the next few months.

Subcommittee on Oil Circuit Breakers

There was presented at the Winter Convention, a paper entitled *Tests on High- and Low-Voltage Oil Circuit Breakers Conducted by the American Gas & Electric Company,* prepared by Philip Sporn and Harry P. St. Clair. This paper may properly be classed as research work, since it gives valuable information on the subject of rupturing capacity of oil circuit breakers and methods which may be used in determining what these capacities are. This is the most important problem in the matter of oil circuit breaker design, and needs much additional research work of this class. Several other companies are arranging for similar oil circuit tests, and most of these tests are being conducted according to the recommendation of uniform test procedure, which will insure comparative results and much valuable data.

Arrangements have also been made for and work is nor progressing on the preparation of a joint paper, *Rating and Selection of Oil Circuit Breakers,* which will bring up to date information presented some years ago in a paper of the same title by Messrs. Burnham, Hewlett, and Mahoney.

In the matter of standards, certain changes have been recommended, and are now under consideration by the Standards Committee, in Standards No. 19 and No. 22. Further work on standardization is necessary, in the opinion of the subcommittee, in connection with the temperature rating on switch and circuit breaker contacts and other parts. This work is being carried on as rapidly as possible with other interests that are involved.

We believe that further work in standardization can be accomplished by the study of factors which determine the interrupting duty on oil circuit breakers. This is recommended for future study.

Subcommittee on Protective Relays

During the past year there have been presented under the auspices of this subcommittee, five papers, including:

Automatic Network Relays, by W. K. Bullard,

A-C. Network Relay Characteristics, by D. K. Blake,

Evolution of the Automatic Relay Unit, by J. S. Parsons,

Design and Application of Automatic A-C. Network Units, by G. G. Grissinger,

Ground Relay Protection of Transmission Systems by B. M. Jones and G. B. Dodds.

In studying the question of standardization, there has been prepared a report on current and potential transformer characteristics. The result of this study is presented herewith, and it is recommended that

further consideration be given the subject, with a view to standardizing the limitations of use of current transformers of various characteristics.

Report of the Subcommittee on Current and Potential Transformer Characteristics

By H. M. Rankin, Chairman

1. The purpose of this subcommittee investigation was to determine the effect of very high currents on the characteristics of current and potential transformers, and to specify the nature and extent of information which is necessary to their application to protective relaying. It was the opinion of the members of the subcommittee that the characteristics of potential transformers were not sufficiently affected by high current conditions to warrant investigation from a relaying standpoint. This report, therefore, deals exclusively with current transformers, including both the "instrument type" with multiple primary turns and the "bushing type" with single turn primary.

2. Characteristic ratio curves for current transformers should have a lower limit of one ampere secondary current and an upper limit determined by any one of the following three conditions:

10,000-amperes primary current,
20 times normal rated current,
2 times nominal ratio.

3. Characteristic ratio curves should be furnished for both "instrument" and "bushing" type current transformers for inductive burdens, power factor 0.5, as follows:

15 Volt-amperes
25 " "
50 " "
100 " "
200 " "

All values of volt-amperes given are based on five amperes, 60 cycles. The various loads are also to be specified in ohms resistance and henries inductance.

4. Until further experience may demonstrate that more narrow limits may be adhered to, the manufacturers should furnish, for each type and ratio of current transformer, a characteristic curve which shall be correct within the following limits:

a. $\pm$ 2½ per cent deviation from standard curve up to 1.1 times nominal ratio.

b. $\pm$ 10 per cent deviation from standard curve at 2 times nominal ratio.

c. The deviations at points between 1.1 and 2 times nominal ratio shall be interpolated on a straight line basis.

The manufacturers will, in future, keep a cloe checks on current transformer tests to determine whether the above limits are reasonble or can be decreased. If greater accuracy than the above is required, pending the result of further investigation on the part of the manufacturers, it should be the subject of special request.

5. Change in phase angle under high-current conditions. Some change in phase angle undoubtedly does occur, especially with "bushing" type current transformers in connection with large non-inductive secondary burden. It is thought that under conditions normally met in operation with secondary burdens approximating 0.5 power factor, this change in phase angle will have no serious effect on relaying. Information is lacking, however, on this point and it is recommended that more complete tests be made.

6. Change in wave form under high-current conditions. The following oscillograms show plainly the wave distortion at high currents:

7. Comparison of relay test methods. Fig. 13, shows a comparison of the primary-secondary method to the shunt method of testing relays with "bushing" type current transformers. The curve marked "1-Turn Primary" represents, of course, the actual operating condition of the "bushing" type current transformer. For the curve marked "Shunt Method," the primary ampere-turns are calculated by multiply-

The first four apply to "instrument" transformers and the remainder to "bushing" type transformers. It will be noted that though the distortion occurring under conditions of primary currents and secondary burdens within the range of ordinary operation may not be great enough to seriously affect relay performance, the imposition of excessive secondary burdens may have a decidedly bad effect.

ing the input current by the number of secondary turns on the "bushing" transformer. The "4-Turn Primary" curve shows the discrepancy which may be involved when testing with one-fourth of the primary current through four turns wound on the core. The "bushing" type current transformer chosen in this test was one having a very low ratio and with the secondary turns bunched in a small space on the core, in

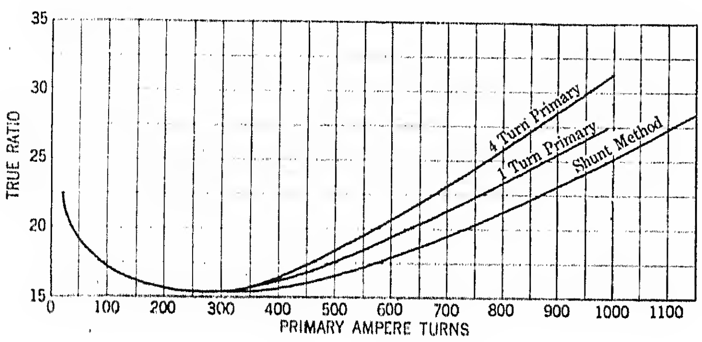

FIG. 13

order to exaggerate the errors involved. With a higher ratio transformer in which the secondary turns would be more evenly distributed around the core, the discrepancies would probably be much reduced.

8. Error due to eccentric location of primary conductor. Fig. 14, which is self-explanatory, shows the effect of eccentric location of the primary lead of a "bushing" type current transformer, combined with the effect of a bunched secondary winding. From a relaying standpoint, the discrepancy is so small as to be negligible.

The attention of the subcommittee for the past year has also been given to the matter of relay test specifications and standards. It has been found difficult to unify the varying practises of the many operating companies, as well as the test methods of the various manufacturers. It is not considered advisable at this time to undertake to offer a final and complete form, but the following data are given as the basis of tentative recommendations by this subcommittee.

1. Nameplate Data.
    a. Descriptive name of relay.
    c. Nominal operating current or voltage, or both.
    c. Frequency.
    d. Calibration curve.
    e. Time setting chart.
    f. Volt-ampere consumption and power factor or resistance and reactance of various coils.
    g. Manufacturer's type or model designation.
    h. Manufacturer's name or mark.
    i. Interrupting capacity of tripping contacts.
    j. Polarity of directional relays.
2. Allowable Temperature Rise.
    a. Coils.
    b. Contacts.
3. Insulation Resistance or Dielectric Strength Test.
    a. Insulation resistance test made with a megger of either 500- or 1000-volt rating.
    b. Dielectric strength test voltage, frequency, and duration of test.
4. Permissible Minimum Contact Separation.
5. Allowable Discrepancy from Nominal Value Given on Taps. (Current or voltage or both.)
6. Zero Torque Test on Zero Power Factor, Current Alone, Voltage Alone, Etc.
7. Chattering Test at High Current.
8. Vibration Tests.

It is hoped that the interested members will comment to the subcommittee on the above suggestion and that by another year, the report may be in the form of a recommended standard. The work of this committee should continue, therefore, for another 12-month period.

It is further recommended that the attention of this subcommittee be directed toward the establishment of other relay standards. This is a subject which deserves considerable attention as there are few phases of the art in general which are really standardized, and the need is great. Other suggested subjects are: Standardization of characteristic curves, standardization of descriptive nomenclature, standardization of relay symbols for single-line diagrams, standardization of relay symbols for wiring diagrams, and standardization of relay operation nomenclature.

It is recommended that a subcommittee be appointed on "Relay Handbook Revisions and Amendments." The book has now been published about two years, and it is believed that sufficient advances and improvements

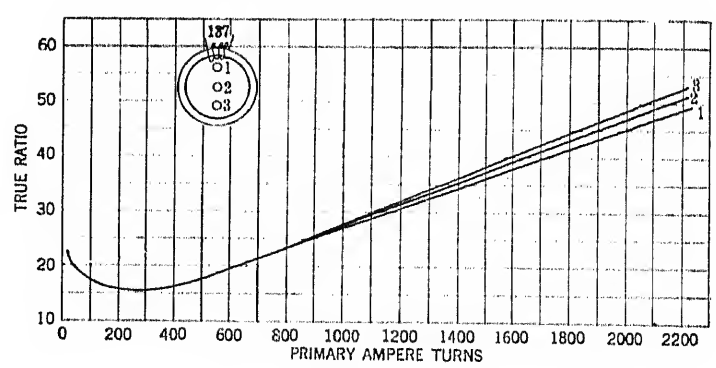

FIG. 14

in the art have occurred to warrant their inclusion in the "Relay Handbook." It is the belief of this subcommittee that such action will be justified every two or three years. Otherwise, the value of the book will disappear in a few years' time by reason of obsolescence.

In the matter of future papers, it is recommended that papers be prepared on the following subjects:

Operating Experience with Impedance Relaying
Operating Experience with Parallel Line Relay, Protection.

F. L. HUNT, *Chairman.*

Discussion

Alfred Herz: I want to mention a few tnings about the klydonograph. This device makes use of photographic emulsion coated on a base of celluloid or glass. The essential thing is the sensitivity of this emulsion.

A photographic emulsion after development will appear as a collection of grains of practically metallic silver. The size of these grains seems to have a direct bearing on the sensitivity of the emulsion. In general as the sensitivity is increased, the grains also increase in size. These grains appear under the miscroscope as separate islands, or clusters of islands with clear spaces between. Films usually supplied for cameras are coated with an emulsion of a fair degree of sensitivity. I believe such films are generally used in the klydonograph. It is possible to obtain emulsions which have practically no grain, such emulsions being usually made with albumin and not gelatine. They are abnormally slow for ordinary photographic work; but they make sensitive surfaces of such a fine grain that they can be used for miscroscopic photographs.

The usual photographic emulsions, made with gelatine, are quite hygroscopic, and I really believe that some caution and research should be carried on as to the effect of atmospheric conditions upon the results obtained with the klydonograph. I feel quite confident that some of the results are influenced by changes in the atmosphere. Therefore, if you want results that are really comparable, it is important first of all to make usé of the same brand and speed of film or plates for all the tests contemplated. Furthermore, the experiments or tests should be carried on under some specific and similar conditions of the atmosphere.

I believe the Lichtenberg figures are produced by minute electric discharges between the grains mentioned, which will account for the ray-like images we obtain under certain conditions as well as for some of the figures resembling tree-like growth.

J. Allen Johnson: I wish to call attention to the matter of lightning-arrester standardization. It appears that by the use of the klydonograph (which you may call an approximately accurate instrument) and the Dufour oscillograph (which is probably a very accurate instrument) the fog which has for so many years surrounded the lightning-arrester question is gradually being dissipated. The difficulties in the way of the standardization of lightning arresters and lightning-arrester tests appear to be passing away. However, the lightning arrester is a device for dealing with transient voltages, for its protective value bears a relation to the transient voltage, not to the cyclic voltage which we generate on our lines. It therefore seems necessary, in order to standardize lightning-arrester characteristics, that we first standardize a transient voltage. That idea may sound revolutionary as we have always been accustomed to thinking of transient voltages as very uncertain in their nature, but the use of the klydonograph is beginning to give us pretty good evidence as to the true nature of the surges which occur on transmission lines. We find, for instance, that they are usually unidirectional, or, if not, highly damped. We are beginning to have evidence as to the steepness of their wave fronts.

It seems, therefore, that the time is nearly ripe to standardize a lightning surge for comparative tests of lightning arresters. This report suggests a definition of a standard surge.

I wish to announce that the lightning arrester subcommittee would be very glad to have any ideas on this subject so that the committee may have the benefit of them in working out this standardization. The committee has prepared a tentative form of standards for lightning arresters based upon—that is, starting from the basis of the report of the working committee in 1926. I have about twenty-five copies of this tentative form and I should be glad to give copies to any one sufficiently interested.

Iron and Steel Industry

Annual Report of Committee on Applications to Iron and Steel Production*

To the Board of Directors:

The importance of electricity to the production of iron and steel has reached such magnitude that this Committee believes that all engineers should be informed as to the situation so as to be prepared to apply it successfully in all its fields of application. To this end, the Committee would outline the extent to which electricity is being applied in this industry.

Lighting

Perhaps the first application was that to lighting. The arcs were replaced by incandescent lamps and now illumination is receiving much attention as to the proper lighting of various jobs and work spaces. Proper illumination is now credited with increase in both production and safety. Steel mills, however, are not yet lighted as they should be, and increased emphasis should be placed on this phase of their work by electrical engineers.

Heating

The use of electricity for heating has increased with the installation during the past year of over 25 melting furnaces. These range from ¼ ton to 25 tons, and are of the arc type. The time of melt has been reduced considerably. The increase of production has also been greatly influenced by furnace design. The removable roof type of furnace appears to be the trend in design.

Resistor type furnaces are being used for annealing and for heat treating of alloy steels. Laboratory furnaces have been used in the steel mills for many years.

Several years ago electrical heating was applied to rolls in sheet and tin mills to increase production during the first turn after a shut down or a roll change. This use is apparently well grounded since a report by the A. I. & S. E. E. states that 168 roll heaters are in use in 19 plants. Electrical heating devices have been used in crane cabs and offices for many years.

Main Roll Drives

During 1926 nearly 150 main roll drives were purchased, all of which were electrically operated. Of these only six were a-c., the rest were d-c., ranging from 230 to 900 volts. Of a special interest is the 8000-hp., 700-volt reversing, d-c. motor drive for the 54-in. blooming mill in a Pittsburgh mill. Large motors for such drives have become common. Individual motor drives on tandem strip mills are also of interest because of their increased use. While the use of d-c. motors has predominated, a few induction motors have been installed with speed control; also, a few large synchronous motors have been applied with apparent success on their particular mills. Undoubtedly, the use of synchronous motors for mill drive will increase.

To reduction of labor and the actual improvement in the steel produced is due the importance of the electrification of steel mills. Electric drives in steel mills permit the mill designer to produce a mill that will do things heretofore impossible.

Auxiliary Mill Drives

In connection with the installation of many new main mill drives, auxiliary drives have come in for much attention, with the idea of giving closer control of these auxiliaries with fewer operators. Automatic control of screw-downs, tables, transfer cars, and drag-overs, together with furnace doors and pit covers, has increased with resultant efficiency, the ratio of steel production to men employed.

The A. I. & S. E. E. has completed its specifications for auxiliary and mill motors and one motor manufacturer has announced motors built according to these new specifications.

Alternating current is gaining some ground applied to auxiliary drives, but direct current is apparently very well grounded in the steel mill electrical man's scheme of operations.

Welding

Electric welding can be mentioned briefly because it is used extensively for repair work, and indications are that in the future building construction will be influenced by this process.

Perhaps the most important application of electric welding is its use for the building up of large machines by welding plates. These welded structures are to replace castings. The ease with which complicated as well as simple structures can be made, together with their lightness and strength, is making this innovation one of importance and one which gives promise of rapidly increasing use.

Safety

Because of the wide-spread use of electricity in mills, the various electrical departments appear to be leaders in safety programs and the elimination of *all* hazards as well as those electrical. This may be because of the

peculiar nature of electrical hazards, and the extensive steps taken by power companies and electricity users to eliminate these hazards and to take care of unfortunate victims. The prominent place of steel mill electrical men in the promotion of safety should be recognized.

Measurements and Instruments

The metering of electric power has been practised from the first, and its convenience has caused its more extensive use in the mills in order to determine not only the total power costs, but also the detailed operating costs down to individual machines and drives. Even auxiliary drive controllers are being specified to include permanent shunts for convenient metering. This permits proper distribution of costs for different processes.

Electricity also plays an important part in other than power measurements, such as tachometers and pyrometers for speed and temperature determinations. The metering of gases is done also readily with great convenience by electrical means.

By the increased use of electrical power measurements attention has been called to economies that are possible. These economies are watched by all departments and stimulate effort by department heads to make savings heretofore uncontemplated. Furthermore, these measurements and economies stimulate improvement of design to affect even greater economies.

Conclusion

In conclusion, it may be noted that there is considerable activity in the rebuilding of steel mills so as to produce more steel at a lower cost. The old steam drives are replaced by electric drives, most of which are for direct current.

The transmission of electric power at high voltages, together with the ease with which it can be converted for convenient application, has caused the use of electricity to drive out steam. Its use is now amply safeguarded and engineers and operators are more skilled in its application and use. The ease with which a few mill operators can control a large number of motors through remote-control devices further demonstrates the superiority of the electric dr've This rapidly increasing use of electric power demands the closest attention of electrical engineers.

The improvement in engineering that is apparent today gives a certainty of predetermination of results which is not only gratifying to the engineer, but of greatest value to the executive.

Economic Aspects of Electricity in Mining Work

Annual Report of Committee on Applications to Mining*

To the Board of Directors:

The applications of electricity in the mining industry, especially in coal mining, have shown a marked increase during the past year, due principally to the fact that its use is an important element in the solution of the problem of high mining costs. These adverse economic conditions have forcibly brought to the attention of mine managers the necessity of replacing expensive labor by electrically operated mechanical devices.

Coal loading machinery operated by electricity has demonstrated its entire practicability and has shown a saving of 25 to 35 cents per ton in mining costs. Much study still remains to be made concerning the question of coordinating machine loading and mining methods. This new and concentrated use of power in a certain section of a mine means a complete reconstruction of the power system, in order to obtain a good voltage regulation for not only the new equipment but for the old as well.

An armoured cable capable of delivering 3000 kw. of power at 4000 volts and 80 per cent power factor has been recently installed in a metal mine shaft 5000 ft. deep. The lowering of a cable of this size into a vertical shaft and its proper clamping to the supporting timbers were problems solved in delivering a big block of power to the bottom of a deep shaft.

In gaseous coal mines where ventilating fans are electrically operated by power obtained from extensive high-tension systems, it is necessary to provide an emergency source of power to operate the fan in case of the failure of the normal power supply. A successful installation of this type was placed in service during the past year, and it consists of a gasoline-engine-driven generator set which will supply power to the emergency motor connected to the double extending fan shaft. After a failure of the normal source of power, 30 sec. are required to automatically start the gas engine set and restore normal fan service.

The use of storage battery power trucks with a capacity of about 150 kw-hr. for operating coal cutting machinery is increasing. Installations of this type result in an increase in the number of places cut and an improved load factor of the power system, providing good judgment is exercised in selecting the time at which the battery is charged. In gaseous mines, the use of battery power not only for cutting, but for pumping and hauling as well, introduces an element of safety heretofore unobtainable.

Automatic starting equipment has been successfully applied to pumping plants, converting apparatus and fans, and lately, air compressors have been operated without attendants. Successful applications of automatic starting equipment have been made to two- and three-speed induction motors, notwithstanding the complicated electrical layout which an installation of this type involves.

Improvements in the haulage systems are being effected by the use of gathering locomotives designed to operate at a slower speed than during the past. The converting equipment required for haulage locomotives is being placed nearer to the load centers, thereby improving the voltage regulation. In mines where a very large tonnage must be transported through a single outlet, belt conveyors have been installed which have demonstrated their value under the above mentioned special conditions.

Many installations of electrical shovels have been made in the metal mining industry, and more recently, the coal mining industry is using this type of shovel. The Ward Leonard control on the large shovels and a motor-generator set with d-c. motors on the smaller shovels show the trend in the electrical apparatus used on shovels.

The work of the United States Bureau of Mines in listing the permissible electrical equipment for use in gaseous mines is one which deserves the commendation and support of all those interested in the safe operation of coal mines. The list is growing rapidly and at the present time it is so complete that a mine manager may select permissible equipment for practically every application in mining. The equipment shows good design and a low maintenance cost. The fact that the Bureau of Mines has approved as much equipment during the past two years as was approved during the previous 10 years is proof sufficient that its work is being valued by the mining industry.

That electricity is being applied in the development of mine safety appliances is shown in the recently developed methane detecting device. Briefly, it consists of a platinum filament mounted on the end of a stick, a battery, and an indicator carried on the inspector's belt. Current from the battery is passed through the filament and it is heated to a constant temperature. The presence of methane or other hydrocarbon gas around the filament increases its temperature

and this is indicated on a dial graduated to show the amount of methane in the air. Indicators may be permanently located in an airway and can be wired to a device in the mine office which will ring a bell when the methane rises above the point which is considered safe. Explosions are prevented by protecting the coil by gauze bonnets such as are used in the Davy safety lamp. The results obtained from this apparatus are very satisfactory.

Further development of the miner's cap lamp has doubled the light available. Judging from the increased efficiency obtained from factory workers when the illumination is increased, there is no doubt that the increase in light furnished to the workers in the "darkest factory" in the world will result in an increase in safety, and efficiency as well.

When one considers that 80 per cent of the American mines are electrified, it seems reasonable to conclude that this accomplishment has been helpful in reducing operating costs.

Such a general adoption of electrical power by mines where the equipment is subjected to damp and gaseous mine air shows that the manufacturers have done their part in designing equipment to meet the conditions. The commercial power companies have also helped in that they are usually in a position to serve a mine with power even if it is located in an isolated section.

W. H. LESSER, *Chairman.*

Discussion

A. M. MacCutcheon: I should like to ask the committee if they can give us any more detail on the progress in getting apparatus approved with an unqualified approval of the Bureau of Mines. As I understand it, they give limited approval to certain types of apparatus. I have not yet learned that they give unqualified approval of types for use in gaseous mines. In talking to the people of the Bureau of Mines at Pittsburgh about two years ago, my conception was that they are approving apparatus because it is the best there is, but it is not thoroughly satisfactory. They said that if they used tests that they would be satisfied with, there was nothing on the market that would stand them. They said, "We are not giving unqualified approval. When we get the right kind of apparatus, we will give unqualified approval." I was wondering if apparatus now gets unqualified approval.

E. J. Gealy: Under the subject of permissible equipment, the industry is today getting much equipment which it has needed for a long time. Every piece of permissible equipment is given what the Bureau calls a "permissible approval plate." That is, it is approved only as long as it is kept in the condition in which the Bureau had it when it was inspected, so it is what you might call "limited."

Aside from that, there is being developed other equipment which is not strictly permissible, but is of a better type for mining service. That will probably result in what we might call "a semi-permissible type of apparatus."

W. H. Lesser: The only question to be answered was Mr. MacCutcheon's question, and Mr. Gealy answered that. I don't know now whether the Bureau of Mines will issue a plate showing unqualified approval.

Marine Work

Annual Report of Committee on Applications to Marine Work*

To the Board of Directors:

The committee in making its report this year does so with a feeling that its efforts to raise the standards of marine electrical installations and increase the utilization of this most efficient, flexible, and safe form of energy, appear more assured than at any time before.

The untiring efforts of the committee as a whole, and individually of the members, with the section of the industry they represent, have, by the dissemination of information, removed to a large extent the opposition and indifference to electric drives, which has been due to a lack of information, and experience in the past, on the part of the owners and operators.

An equally deciding factor, and one for which the committee hereby desires to acknowledge its appreciation, has been the recognition accorded by various bodies covering inspection, classification, and insurance; *viz.*, United States Government Departments, American Bureau of Shipping, National Board of Fire Underwriters, National Fire Protection Association, and similar associations, thus establishing complete harmony in the endeavor to increase the usefulness of electricity, surrounded by the necessary safeguards.

Electric drive is not only gaining headway in its application to deck machinery, engine room auxiliaries, and cargo pumps, but also as a means of propulsion for tugboats, ferryboats, and all classes of vessels where frequent starting and stopping is necessary, and where large torques are required at minimum speeds. This headway has been due to a careful study of the particular application by the designing and operating engineers and to the hearty cooperation of the electrical manufacturers to build special apparatus, where standards were not the most suitable and advantageous, and there is every evidence of a continuance of this spirit.

It will be recalled that in 1920, the Institute issued a volume; *Recommended Practise for Electrical Installations on Shipboard*, which was accepted and used by a great majority of the naval architects, marine engineers, ship owners and shipbuilders, and recognized by the Insurance and Classification Societies as having filled a long-felt want. The committee takes pleasure in announcing that after three years of close application to the study of revision, the Institute will at an early date issue the revised edition which represents the combined efforts of representatives from United States Navy Department, Classification and Insurance Societies, electrical manufacturers, and shipbuilders, for which sincere appreciation, by the Institute and the committee, is hereby acknowledged.

Arrangements are being made to give this edition wide circulation; first, that it may add to the simplification and standardization movement which is being so urgently advocated by the United States Government Department of Commerce, and secondly, that the Institute's standards may be universally adopted, which ultimately will result in better products of uniform manufacture at lower first costs and maintenance.

The economic feature of shipbuilding is at a low ebb and has not materially changed since the war; furthermore, there is little hope of any relief until some changes are made in our shipping laws.

Shipbuilders and owners of the United States cannot hope to compete with those of any other country, owing to material and labor prices. Our shipping laws provide protection only in the coastwise trade, and necessarily the advantages of electric drives which originated, and have been highly developed in this country, have opportunity for demonstration only in that class of vessels.

Electrical Transportation

Annual Report of Committee on Transportation*

To the Board of Directors:

During the past year the application of electrical means to the various branches of transportation continued at an accelerated pace. The major division of the transportation industry, namely, steam railroads, added to its electrified lines and, although the mileage electrified is still a small percentage of the total, it is steadily increasing and is rapidly becoming an important factor in railroad operation. Into the field of city and suburban railways, improvements are constantly being introduced. On the water, electric drives are being adopted more and more, with either steam turbines or oil engines as prime movers. Bus transportation is adopting, extensively, gas-electric propulsion. The oil-electric locomotive and the gas-electric motor rail car are being introduced in certain phases of railroad operation.

Steam Railroad Electrification

The year 1926 has seen the completion of two major electrification projects, that of the suburban lines of the Illinois Central Railroad out of Chicago and the line of the Virginian Railway between Mullens, West Virginia, and Roanoke, Virginia. The Detroit & Ironton Railroad completed 17 mi. of electrification between Fordson and Flat Rock, Michigan.

The New York Central opened a new electrified section between High Bridge and Yonkers, New York.

Of the principal uncompleted projects, the Great Northern Railway is electrifying 80 continuous mi. of its line between Wenatchee and Skykomish, Washington. The Pennsylvania Railroad is extending electric suburban operation on its main line between Philadelphia and Wilmington, and also from Philadelphia to West Chester. The New York, Westchester, & Boston Railway is continuing its extension of electrified line between Larchmont and Port Chester, New York. The Long Island Railroad is installing freight electrification on its Bay Ridge division.

Illinois Central Railroad. The first step in the electrification of the Illinois Central out of Chicago was completed during July of last year when the suburban service was placed in electric operation over 28 mi. of the main line and 8.9 mi. on two branch lines. The ordinance under which this project was carried out calls for electrification of freight service within the city limits by 1935 and electrification of through-passenger service on both the Illinois Central and Michigan Central by 1940, provided a certain portion of the tenant roads then using the passenger station on East Roosevelt Boulevard are electrically operated at the time.

The 1500-volt, d-c. system with overhead contact wire was chosen since there is no immediate prospect for extension over main line divisions.

Power supply is secured at the railroad's right-of-way from substations owned and operated by outside power companies. The conversion from 60-cycle power to 1500-volt direct current is accomplished by means of synchronous converters and mercury arc rectifiers. One of the reasons for purchasing power rather than building a generating plant was the fact that the power companies can supply power from several plants over various routes and thus aid in securing continuity of service.

The distribution system of the railroad is so laid out that the wires over each track are separate electrically and can be sectionalized at substations and interlocking plants by automatic high-speed circuit breakers. Normally, the wires are tied together over all tracks. No feeders are required external to the catenary system. Trolley feeder switches in all substations and tie stations are operated from the railroad company's power supervisor's office by supervisory control. The power supervisor has electrical indication from each substation and tie station and, in case of trouble, he can cooperate with the train dispatcher who occupies a joint office.

The catenary system, which provides the entire current-carrying capacity, has an average conductivity over each track of about 790,000 cir. mils, copper equivalent. This figure takes into consideration average wear on the contact wire. The catenary system is completely non-ferrous, with a double contact wire. Chord construction is used on curves with the aid of shortened pole spacing. The rail bond, adopted as a final standard, is a U-type gas-weld bond consisting of two No. 1 A. w. g. flexible conductors.

The 260 multiple-unit cars for this service are built in two-car units. Two pantographs and four 250-hp. nominal-rating, self-ventilated, series railway motors are located on each motor car to which a trailer car is semi-permanently attached. Normally, only one pantograph on each motor car is in operation. Each pantograph exerts a pressure of about 20 lb. against the contact wires. Automatic couplers couple the cars together mechanically, electrically, and pneumatically with full automatic operation between the two-car units.

Virginian Railway. Heavy electric freight operation over the entire electrified zone of the Virginian Railway

*Committee on Transportation:

J. V. B. Duer, Chairman

E. R. Hill,	H. A. Kidder,	N. W. Storer,
W. K. Howe,	John Murphy,	W. M. Vandersluis,
D. C. Jackson,	W. S. Murray,	Richard H. Wheeler.
	W. B. Potter,	

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

started in September, 1926. The electrification is now complete from Mullens, West Virginia, to Roanoke, Virginia, a route of 133 mi.

An 11,000-volt, 25-cycle, single-phase, a-c. system is installed. The problem of taking a heavy tonnage train down a long grade was a large factor in deciding upon the a-c. system in order to use split-phase locomotives for regenerative braking.

The power plant, owned and operated by the railway, contains four 12,500-kv-a., 25-cycle, single-phase turbo generators and five water tube boilers each rated at 1521 b. hp. Pulverized fuel is used and has been found to be peculiarly well adapted to the rapidly fluctuating power load.

Electric power is transmitted from the plant at 88,000 volts over twin transmission lines. There are seven transformer substations along the right-of-way. They contain three-coil transformers in which the low-voltage winding is divided into two parts. One part of the winding supplies 11,000 volts between the trolley and rail, while the other part supplies 22,000 volts between a feeder and the rail. This gives a potential between trolley and feeder of 33,000 volts. Transformer windings are so constructed that reconnection for 22,000 volts from trolley to ground can be made when traffic demands require this to be done. Balancer stations containing auto-transformers are located between the main transformer stations in order to connect the feeder circuit to the trolley and rail.

The catenary system is completely non-ferrous with a copper and bronze composite messenger and a bronze contact wire. Inclined catenary is used in general, but on account of the great number and high degree of curves, pull-offs have also been employed.

The 12 road locomotives are each built in three units which are electrically identical. They receive power from the single-phase trolley through a transformer and phase converter, and are driven by three-phase traction motors at running speeds of 14 and 28 mi. per hr. Each complete locomotive weighs 637 tons.

Detroit & Ironton Railway. During 1926, the Detroit and Ironton Railway started electric operation on 17 mi. of line from Fordson to Flat Rock, Michigan.

Power is supplied at 44,000 volts, 25-cycle, single-phase, between feeder and contact wire, with 22,000 volts between contact wire and ground.

The catenary system is non-ferrous, composed of 4/0 bronze contact wire and a ½-in., seven-stand bronze messenger wire. The supports for the catenary are unique in that they are pre-cast reinforced concrete arches bolted together and placed on concrete foundations. Inclined catenary is used on curves. A ½-in. stranded copper feeder, together with auto-transformers, is used to secure three-wire feed.

The locomotives, two in number, are of the motor-generator type. In these locomotives, alternating current is stepped down to 1240 volts to drive a synchronous motor which, in turn, drives a 600-volt d-c. generator. Eight traction motors, of the d-c. type, rated at 225 hp., are mounted on each power unit which is articulated into two wheel bases of four axles each. The complete locomotive consists of the two power units. It has 32 driving wheels on which the total weight of 372 tons is carried.

Great Northern Railway. The line of the Great Northern Railway between Wenatchee and Skykomish, Washington, involving about 80 mi. of route, is being electrified with 11,000-volt, single-phase, alternating current. Twenty-six miles of the old line (from Cascade to Skykomish) is now in operation. A new tunnel 7¾ mi. long is being constructed to improve the route and to replace the old Cascade tunnel which was electrified in 1909 with 6600 volts, three-phase.

Two motor-generator type locomotives with two cabs each have been placed in service, which convert the 25-cycle power into 600-volt direct current to operate the traction motors. These two locomotives have a continuous rating of 3660 hp. at 15½ mi. per hr. with a tractive force of 88,500 lb.

Two single cab motor-generator type locomotives are now being built. They will convert the 25-cycle power to 1500-volt direct current to operate the motors with two motors in series. These locomotives will have a continuous rating of 3000 hp. at 18.6 mi. per hr. with a tractive force of 60,500 lb.

Pennsylvania Railroad. The Pennsylvania Railroad has under way the electrification of its main line for suburban service between Philadelphia and Wilmington, a distance of 27 mi. After this is completed, the suburban line between Philadelphia and West Chester will also be electrified. The design is laid out with due regard to the possibility of future extensions.

Electric power will be purchased, stepped up, and transmitted along the right-of-way at 132,000 volts, 25-cycle, single-phase, 66,000 volts to ground, over duplicate transmission lines to the transformer substations where it will be converted to 11,000 volts for the trolleys.

The catenary system will be completely non-ferrous. A bronze messenger wire with copper auxiliary wire and a single bronze contact wire will be used. The inclined type of catenary is to be installed on curves. The catenary supports are principally back guyed tubular poles with cross-span catenary to support the main catenary.

Multiple-unit cars of the type in the existing suburban electrification to Paoli and Chestnut Hill will be used.

New York, Westchester, & Boston Railway. The New York, Westchester, and Boston Railway has built an extension of its line to Harrison, New York, and will continue on to Port Chester. Much of this extension adjoins the trackage of the New York, New Haven, and Hartford Railroad. Multiple-unit suburban service is operated with an 11,000-volt, single-phase system.

Long Island Railroad. The Long Island Railroad is electrifying its freight line to Bay Ridge for 11,000 volts, single-phase, with overhead catenary construction. This involves about 100 mi. of trackage. Seven 150-ton locomotives for operation on this line have been delivered.

The extension of the third rail d-c. electrification over the West Hempstead passenger branch was completed last October.

New York Central Railroad. During 1926, the New York Central opened electric operation for multiple-unit service on the Putnam division, extending from Sedgwick Avenue Station, New York City, to Yonkers, New York, a distance of seven mi.

City and Suburban Railways

New car equipment being placed in service on electric railways is now confined, in most cases, to the light-weight type of car, in order to secure reduced operating costs.

Articulated train units are now in operation in street-car and subway service. Three-car articulated units for heavy subway and elevated service have been installed by the Brooklyn-Manhattan Transit Corporation. These units consist of three-car-bodies mounted on four trucks.

The most radical development is a car on which high-speed motors, entirely spring-supported, drive the axles through worm gears and a differential. Light weight and absence of noise are the outstanding characteristics of this car.

Marine Propulsion

Diesel-electric drive has been introduced on large tankers, suction and dipper dredges, ferries, and tug-boats. Double-end operation has been successfully introduced on tug-boats as well as on ferries.

Turbo-electric drive has been used on ferries in addition to its past application to large boats.

Bus Transportation

Simplicity, ease of control, and durability are among the advantages which are causing the rapid introduction of gas-electric drive on buses.

Recent Developments

Diesel Electric Locomotive. The Diesel engine prime mover with electric drive is finding an increasing field in moderate sized locomotives up to 1000 hp., on account of its high efficiency, ease and flexibility of operation, and the absence of stand-by losses.

Gas-Electric Cars. Many of the gasoline-propelled rail cars now being placed in operation are equipped with electric drive.

Automatic Substations and Supervisory Control. The automatic substation is now finding its way into the electric railway field. The New York Central Railroad is installing three such substations to supply additional power for its New York Terminal electrification.

Supervisory control has been introduced by several of the recently completed railway electrifications, notably the suburban electrification of the Illinois Central, out of Chicago.

High-Speed D-C. Circuit Breaker. The high-speed d-c. circuit breaker, on account of the fact that it is opened by the rate of increase of the current rather than by the current value, has two distinct advantages in railroad electrification. First, the breaker will open before the current has reached a damaging value in any abnormal condition, such as motor flashovers, severe wheel sliping, or slight grounds. Second, the rapid rate of rise of current in a short circuit of any value makes the breaker more susceptible to short circuits than to heavy power loads and thus aids in securing selectivity between these two conditions.

Mercury Arc Rectifiers. The installation of mercury arc rectifiers for the Illinois Central is one of the first instances in which these rectifiers have been used in this country for a steam railroad electrification.

Motor-Generator Locomotives. Motor-generator locomotives are being placed in service by the Detroit and Ironton, Great Northern, and New York, New Haven, & Hartford Railroads. This type of locomotive can be built to give regenerative braking down to a very low speed. Speed control is flexible and the a-c. synchronous motor operates at a high power factor while the d-c. traction motors are developed to a high degree of efficiency.

Test Plant for Single-Phase Locomotives and Cars. In order to test electric locomotives and multiple-unit cars, the Pennsylvania Railroad, during 1925, equipped its Locomotive Test Plant at Altoona with a motor-generator set to convert 11,000-volt, three-phase, 60-cycle power into 11,000-volt, 25-cycle, single-phase power. A 204-ton freight and passenger locomotive was tested in 1925. During the year 1926, a complete test was made with a multiple-unit car.

New Single-Phase Induction Motor. A single-phase traction motor without a commutator has been built in Germany. It consists of two rotors on the same axis, one inside the other. The outer rotor is synchronous, excited by direct current. The inner rotor is a slip-ring motor which drives the shaft. According to the builders, power factor can be maintained at unity with this motor, and it is their hope that the motor will compete successfully with the a-c. commutator motor.

Technical Papers

The committee has been fortunate in securing some excellent papers for presentation at the Summer Convention in Detroit. They are as follows:

Current Collection from an Overhead Contact System Applied to Railroad Operation, S. M. Viele, Pennsylvania Railroad.

Catenary Design for Overhead Contact Systems, H. F. Brown, N. Y., N. H. & H. R. R.

Catenary Construction for Chicago Terminal Electrification of Illinois Central Railroad, J. S. Thorp, Illinois Central Railroad Co.

Collection of Current from Overhead Contact Wires, R. E. Wade and J. J. Linebaugh, General Electric Co.

Railway Inclined-Catenary Standardized Design, O. M. Jorstad, Westinghouse Electric & Manufacturing Co.

J. V. B. Duer, *Chairman*.

Electric Welding

Report of the Committee on Electric Welding*

To the Board of Directors:

It is the object of this report to give to the members of the Institute an idea of the commercial importance of Electric Arc Welding.

In such a report as this, the subject falls into two main divisions: Electric Arc Welding, in which the heat for doing the work comes from an arc drawn between the work and an electrode; and Resistance Welding, in which the heat comes from the electric resistance to the passage of a large alternating current across the abutting edges of the parts to be joined.

Electric Arc Welding is done by the *carbon arc* process and the *metallic arc* process. In the carbon arc process direct current is used and the arc is drawn from the work to a carbon electrode. In the metallic arc process either direct or alternating current may be used, but direct current is generally preferred and the arc is drawn between the work and a metallic rod, which melts into the work.

The carbon arc process was first used, on a commercial scale, fifteen or twenty years ago for the repair of steel castings. It has come to be accepted as the standard method of repair for minor defects in such castings. Practically all the steel foundries use this process and most of the 600,000 tons of steel castings made in this country each year have minor defects repaired by the carbon arc welding process.

Locomotive Boiler Repairs

The metallic arc first came into commercial importance in 1914 in the repair of marine engine parts on some interned German ships. Since that time, this process has been used by the railroads to an increasing extent for the repair of machinery of all sorts.

At the present time, it is safe to say that the locomotive which drew the train that brought you to this Convention had all the flues welded in the works that built the locomotive in the first place, and that the boiler has had some repairs by the metallic welding process made on it in the repair shops of the road owning the engine. The fact that locomotive boiler repairs are so frequently made is very striking evidence of just what the process can do, for electric welds will stand up in a boiler of a locomotive carrying 200 to 250 lb. of steam and traveling over the rails at 60 mi. or more per hour. Electric welding is used for the repair of many parts of the locomotive beside the boiler. It is used for building up worn treads on driving wheels, worn guide bars, repairing broken frames, and for the repair of many other parts of the locomotive.

Mr. Wanamaker, one of the members of your Electric Welding Committee and Director of Welding for the Rock Island Systems has stated that the use of welding has enabled them to make repairs so much more promptly that they are able to get the same service with 20 locomotives less than would have been necessary with the old methods of repair.

To put it another way, welding has enabled the Rock Island System to reduce the investment in locomotives by over $1,000,000 without decreasing the number of engines available for service. This is in addition to the savings effected by the use of welding over the older methods of making the same repairs.

I quote from a letter from Mr. Wanamaker;

> "The latest estimate states that the railroads of this country now have invested approximately $4,000,000 in arc welding equipment, covering some 3500 welding equipments which are saving the railroads approximately $1,000,000 per month, or $12,000,000 per year. It is possible that the indirect savings will be greatly in excess of this figure. However, it is not the policy of railroads to assign a value to the indirect savings.
>
> "The use of electric arc welders for battered rail ends and special work rail is just now beginning to take strong root. I, personally, feel that the intelligent use of the electric arc welder has paid probably the greatest net return ever secured from any investment made in railway equipment, and I am somewhat at a loss as to why its use has not been more strongly furthered and fostered by the A. I. E. E."

Mr. Churchward, another member of your Committee, has a number of photographs showing the repair of an 8000-lb. bronze propeller by the addition of about 1000 lb. of bronze at a great saving in cost; he

---

*Committee on Electric Welding:

J. C. Lincoln, Chairman

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

also has some photographs of the building up of the copper collector rings of a 1000-kw. rotary.

As important in repair and replacement work as is the use of electric welding, recent experience shows that its greatest field is as a new method of manufacture of new products.

It is clear that if a welded joint in steel can be made equal in strength to the plates to be joined, great economies in production can be obtained.

Following will be found a number of examples of construction on a large scale, in which welding has replaced riveting and the older methods of joining steel plates.

Shipbuilding

So far as we know, the first all-welded vessel was built in Ashtabula, Ohio, about 1914, for use on the Lakes. This was a boat 40 or 50 ft. long, used as a fishing boat. It has been in satisfactory service ever since it was built. On one occasion, a year or so after it was built, the plates near the waterline were bent by smashing through ice on the Lake, but no joint opened up.

Mr. James W. Owens, one of the members of your Committee and who, until his association with the Newport News shipbuilding & Dry Dock Company as its Director of Welding, was in charge of Welding Research and development for the U. S. Navy, says:

> "The Navy's investigations of welding at the Norfolk Yard have resulted in increased confidence of the Department in welding, with the result that it is now being used extensively in new construction and repair of naval ships. Its battle towing targets, which are 45-ton structures and of ⅜-in., ½-in. and 1-in. plate material, are now completely metal arc welded, 15 such targets being constructed to date. The shell deck and two water-tight bulk-heads of a pontoon for a 100-ton derrick have been completely welded. It is being extensively used in the construction of the light cruisers recently authorized by Congress, and an estimated saving of $250,000 is being secured by its use in the modernization of its capital ships.
>
> "The Coast Guard Cutter *Northern* which was recently launched at the Newport News shipyard, has its deck and superstructure very largely metal arc welded. Its rudder is completely welded and four seams at the waterline are welded in addition to being riveted in the usual manner, so as to enable the hull to more effectively resist ice pressure in Arctic service. Practically all oil, gas, and fresh and salt water tanks of ships being built at this yard, together with their piping systems, are being welded, and steps have been taken to completely weld all of the ventilating system ducts. During 1926 a total of 165 welded tanks was built and it is becoming standard practise to weld deck beams directly to bulkheads with or without the use of plate collars. Two completely welded condenser shells for merchant ships have recently been completed, together with the exhaust pipes for several ships."

Welding Structural Steel for Buildings

The steel frames for a number of buildings have been made by the arc welding process. In 1925 a three-story garage building, having a ground area of about 75 by 150 ft., was erected by the Wellman-Seaver-Morgan Company of Cleveland in Canton, Ohio. Although this was the first building arc welded by this firm, no difficulty was experienced in the erection, and they report a saving of 25 per cent in cost of erection, as compared with the cost of the same building riveted.

The largest building erected by arc welding to date has been that erected by the Westinghouse Electric & Manufacturing Company of Sharon, Pa. Mr. A. M. Candy, a member of your Welding Committee, was in general charge of the work and has written a very complete and valuable paper describing the work.

The building at the Sharon, Pa., Works of the Westinghouse Electric & Manufacturing Company is 70 by 220 ft., by 80 ft. high and required 790 tons of metal.

The following are some extracts from his paper:

> "That arc welded joints can be constructed in such manner as to develop fully the ultimate strength of the structural members connected.
>
> "That a steel I-beam of given section and length will sustain a far greater load if fixed at its ends by a suitably designed arc welded joint than if supported by standard riveted connections consisting of top and bottom angles. A 9-in. standard I-beam framed between rigid upright columns 8 ft. apart by means of specially designed welded connections sustained a load 25 per cent greater than a beam of the same size and length framed between columns by means of riveted top and bottom angles ½ in. thick.
>
> "A plate girder, assembled by welding and consisting of nothing but sheared plates has a far greater strength than a riveted plate and angle girder of the same weight, due to the better distribution of the steel in the cross section. A 15-in. plate girder, assembled by welding and simply supported on a 14-ft. span, developed more than 50 per cent greater strength than a riveted plate and angle girder of the same depth and the same weight.

"The prevailing impression among the witnesses was that these tests demonstrated the superiority of welded connections to riveted connections in every case where direct comparisons were made, and brought out two general facts:

"1. That complete continuity of lines of beams can be obtained in welded construction, whereas it is well known that this cannot be done in riveted construction.

"2. That in a welded building it will be possible to make every joint develop full strength of the main members, whereas in a riveted building many joints are weaker than the members due to the weakening effects of the rivet holes and the weakness of steel angles which have to be used for transmitting tension between two members at right angles to each other.

"It was proved that a welded plate girder was 50 per cent stronger than the riveted girder of relative depth, length, and weight.

"An Olsen testing machine, capable of applying 40,000 lb., was used."

In 1924 near Toronto, Canada, a highway bridge nearly 700 ft. long was erected by arc welding.

The American Welding Society has an active committee on Structural Steel Welding, the chairman of which is Mr. James H. Edwards, of the American Bridge Company. This committee is collecting data and making extensive tests to provide structural engineers with the fundamental information necessary to properly design an arc welded structure. The work of this committee is to provide the structural engineers with the information as to how long a weld and how thick a weld to use to give a strength of joint equal to the strength of the members being joined.

Pipe Lines

The carbon arc has been used for the manufacture of almost 90 mi. of pipe nearly six feet in diameter, for supplying water to Oakland, California, and the other Bay Cities in the vicinity.

Following are some quotations from a paper read by J. F. Lincoln, March 17th, 1927:

"As an illustration, The Mokelumne River pipe line which was made arc welded, is 90 mi. long and contains 78,000 tons of steel. If this same pipe line with the same strength of joint and the same ability to carry water had been made riveted, it would have required 128,000 tons of steel to accomplish the purpose, and the cost would be at least $3,000,000 more.

"The best illustration of the economic advantages of the above ideas are shown in the Mokelumne River Pipe Line, which brings the water supply a distance of 90 mi. to the East Bay Municipal Utility District in California. This line runs from the Mokelumne River to Oakland and supplies the water for all of the Bay Cities, with the exception of San Francisco. This job required, for the manufacture of the pipe, 78,000 tons of steel, the thickness of this steel being 3/8 in., 7/16 in., 1/2 in., 9/16 in., and 5/8 in., depending upon the part of the line in which the pipe was to be placed. It was manufactured in two lines—the first running from the San Juaquin River to Oakland and the second, from the Mokelumne River to the San Juaquin River.

"The first section of this, running from the San Juaquin River to Oakland, is at the present time completed and has been under pressure now for a considerable period. Because of the newness of arc welding, the engineers determined not to proceed with the second section of this pipe line until after the first section had been completed. They have, within the last sixty days, let the contracts for the second section, the specifications remaining identical in every particular with those of the first, thus showing the complete success of this method of construction.

"It is also interesting to note that, in spite of the fact that no such work as this had ever before been attempted, in so far as thickness of plate, diameter of pipe, etc., were concerned, the first 40 mi. were completed more than one month ahead of time, and this in the face of the fact that the building for the manufacture of this pipe had to be constructed, machines designed and built, and the whole plant put into operation.

"The second section of this line, which is to be done in the same time as the first, will undoubtedly beat its schedule by many months.

"The description of this line and of the problems involved, as concerns welding, can probably best be explained from the specifications which were drawn for it and under which the pipe was manufactured. The specifications covering the welding machines provided that the welding shall be done with an automatic electric welding machine, designed specifically for the work covered by those specifications. This machine comprised among other necessary parts, a traveling carriage for carrying the carbon electrode, arranged to move, at a controlled rate, along a tract located inside of the pipe above the bottom seam, and water-cooled mandrels located on the outside and inside of the pipe and extending along this seam throughout its length.

"Next, the method of testing was specified as follows:

"*Hydrostatic Test of Pipe Specimens.* After each section of the pipe has been welded, it shall be subjected to a hydrostatic test under internal pressure sufficient to develop a tensile stress of 20,250 lb. per sq. in. of plate, and while under this stress, shall be hammered vigorously on both sides of the weld with a 10-lb. hammer not more than once in every foot of pipe section. The pressure shall then be increased sufficiently to produce a tensile stress of 23,000 lb. per sq. in. of plate and so held until the efficiency of the seams can be determined by inspection. In the event of failure of the pipe section under this test, the contractor shall have the right to re-weld the pipe if practicable and re-submit it for test.

"*Rejection.* Any section of pipe that does not conform to these specifications may be rejected.

"It is claimed, in connection with this, that it is probably the most severe test that was ever put on any pipe made by any process, and it is only necessary to say that possibly no other method of manufacturing large pipe now known could pass the specifications for test as outlined in these specifications. As a matter of fact, there are a number of cases where the test pressures were carried up so high and so far beyond the statement in the specifications, that a permanent set was actually put in the steel of the pipe. In one case that came to the author's attention the diameter was increased by more than three inches because the pressure that was used in testing went considerably beyond the elastic limit of the steel."

Use of Welding to Replace Castings

Due to the fact that rolled steel has three or four times the tensile strength of cast iron, and at the same time costs from one-third to one-fourth as much per pound, it is possible to make many structures from rolled steel shapes by arc welding to replace cast iron at a very great saving in cost.

For instance, a certain cast iron bed plate weighed 560 lb., and at 5.5 cents per lb., cost $30.80. The cost of machining this was 90 cents, making a total cost of $31.70.

The corresponding base of angle iron welded up (with bosses welded in) weighed 233 lb., cost $6.38 for material and $1.07 for cutting off, welding, and drilling, or a total of $7.45. In addition, the welded base will stand any abuse that can be given to it, while cast iron bases break if not carefully handled

One of the first welded products we happened to know about was a compensator can. This can was formerly made of cast iron, very heavy, very expensive, and liable to leaks which made it necessary to reject part of those the foundry delivered. The arc welded can, for the same purpose, looked better, weighed less than 20 per cent of the old cast iron can, and cost less than 10 per cent.

The General Electric and Westinghouse Companies are using arc welding to an increasing extent in the manufacture of their product, though the process can be and no doubt will be used to a much greater extent in the future.

A paper by Mr. Warner, in the March issue of the American Welding Society *Journal,* gives an account of some of the work being done by the General Electric Company at the present time.

The Company with which your Chairman is connected has brought out a book "Arc-Welding, the New Age in Iron and Steel," in which there are hundreds of illustrations of structure of all kinds built by Electric Arc Welding.

This process makes possible the manufacture of many structures that are both better and cheaper than the same structures were when made of cast iron.

Resistance Welding

This process was invented by Elihu Thompson, in the early days of electric development, and at the present time is used for the production of some millions of feet of tubing every month. Practically all of the tubing used in automobiles and in the construction of bedsteads, is made by this process.

As you all known, a million dollars is a small sum when talking about automobile products, and as this process is used to a greater or less extent in the construction of all cars, we can be sure that the cost of the car you drive would be noticeably greater if it were not for the saving in cost of construction made possible by this process. The all-steel automobile body is coming into use and thousands of these bodies are made every year in which the seams are welded by this process.

The following is quoted from a letter from Mr. H. W. Tobey, one of the members of your Committee and in charge of work of this kind at the Pittsfield Works of the General Electric Company:

"Our large spot welders are used in regular production for thicknesses of steel ranging from two pieces of 1/4 in., two pieces of 3/8 in., up to two pieces of 1/2 in., making a maximum total thickness of 1 in. This method has replaced to a very large degree the former practise of riveting.

"Spot welding is also used throughout the plant for a variety of purposes where it is desired to join various parts of equipment together in a strong and effective manner at a reasonable cost.

"Resistance line welding has been found to be of especial value wherever it can be applied in mass production to structures composed of sheet material of suitable shape and in thicknesses up to and including two pieces of 1/8 in. stock.

"All factors entering into the several types of resistance welding, including butt welding, spot welding, and line welding, are under perfect control so that after correct settings have been obtained for current, pressure, speed, etc., the results can be duplicated with unerring regularity as long as the characteristics of metal remain the same. The material is brought to precisely the right temperature and strong, reliable welds uniform in character and appearance are assumed. The fact that no hood or eye protection through the use of colored glass is required, is also a distinct advantage."

J. C. Lincoln, *Chairman.*

Discussion

J. D. Noyes: I should like to ask Mr. Lincoln if the committee has come to a conclusion as to the comparison or disadvantages' between alternating current and direct current.

E. C. Crittenden: Recently there has come to my attention a field in which it appears that some companies are finding other methods better than electric welding. Mr. Wanamaker in the report, says, with regard to railroad practise, "The use of electric arc welders for battered rail ends and special work rail is just now beginning to take strong root." I understand

also that the street railways are using arc welders in putting up crossings and other special work, but for the regular rails, the straight-away welding, they are finding other methods better.

It appears to me that probably the difficulty arises from the fact that they are using the old method of connecting rails with only a slight modification for welding. Two rails abutting, end to end, are held together by two fish-plates. The two plates are clamped on the sides of the rails and then welded around the edges. This method has the effect of stiffening that part of the rail and in service, the rails often break at the end of the welded and stiffened portion, presumably because the stresses are localized there. I believe some companies have abandoned arc welding of rails because they got such breakage. Is there available any electrical welding method which will avoid this difficulty?

F. W. Funk: Mention has been made in the report of several buildings that have been electrically welded. We have in Youngstown a welding company which erected a steel-frame building which was entirely welded; that is, there were no holes punched or drilled—no bolts used in temporary construction. It was a 100 per cent welded building. I think that is quite an advance because if we have to punch structural shapes, it offsets the saving.

Electric welding is coming into use for very heavy plate work and tank work. One concern which manufactures very large oil tanks for use in the oil fields is going into the electrical welding of heavy plate tanks. It is probable that the process will be an automatic welding process.

Another company is producing thousands of tons of complicated rolled shapes each year which are either seam- or lamp-welded, used principally, I think, in floor beams and roof members. I mention this concern particularly because it has done a great deal in the development of automatic welding machines.

I think Mr. Lincoln is entirely correct in saying that in new construction lies the greatest field for electric welding.

J. J. Shoemaker: I should like to ask Mr. Lincoln if this method of welding is approved by the insurance companies for boiler repairs?

J. V. B. Duer: I think some of these questions that have been discussed are important. The question of workmanship enters into electric welding more than most of us realize. I think if we could be assured that the workmanship on an electric weld was perfect, it would be a more generally accepted practise than it is at the present time.

I am also much interested in the question of the relative values of a-c. versus d-c. welding. I made a rather superficial investigation of the subject a few years ago and came to the general conclusion at that time that the principal objection to a-c. welding was that it involved a low power factor on the circuits to which the welders were connected. That was especially true of 60 cycles rather than 25 cycles. In a place where the welding load amounted to a large proportion of the total, such as it might in a roundhouse on a railroad or some place of that kind, the use of an a-c. welder might be objectionable whereas if a d-c. welder were used the high power factor due to the use of the welding might be obtained and some correction made for low power factor on the other circuits.

J. C. Lincoln: I may be prejudiced in favor of the direct current. It happens that the concern with which I am connected, manufactures d-c. apparatus. That fact has to be taken into consideration in weighing my reply. I believe myself that experience will show that it is easier to make a good weld with a good d-c. machine than it is with an a-c. machine. We feel this way about it; that the art would be advanced more rapidly by doing only good work. Therefore, only the best apparatus should be used. I believe, on the average, for metallic arc welding better work can be done with the direct current than with alternating current.

I think it is true that in some cases railroads which have formerly used the electric-arc method for joining their rails are using other methods at the present time. I have been very much interested in that particular part of the electric-welding art for a good many years. Notwithstanding the fact that there have been a number of failures, the amount of success with electric-welded joints has been sufficiently great so that they are used commercially to a great extent. In my opinion, the failures have been due partly to the cause as pointed out by Mr. Crittenden, but more largely to the fact that the welding methods themselves haven't been as good as we hope they will be some time.

In the electric welding of rails, in some cases at the bottom of the crater when the weld is finished there are hair cracks due to the contraction of the hot metal. Now, it is a fact, of course, that hot metal occupies a larger volume than the same metal when cold. Metal, when melted, occupies 107 per cent of the volume it does when cold. When the metal cools, one of two things happens—either the metal must stretch according to the amount of decrease in volume or hair cracks appear. If the metal is brittle enough, hair cracks appear. If the metal is of the proper quality, it will stretch and take up this decrease in volume.

It is my belief that most of the difficulty in the welding of rails has been due to the fact that the methods in use at the present time produce welds which are brittle so that these hair cracks appear.

Now, a hair crack at the end of the rail will start an incipient break. Take, for instance, a piece of glass. You know that if you start a crack in a piece of glass, the wind strains will finally work that crack further and further through the glass. If you will drill a hole at the end of the crack, you won't find any further trouble. The incipient crack doesn't progress. Something of the same nature occurs in the electric welding where the hair cracks appear. The remedy for that condition is to improve the quality of metal in the weld.

It is a fact that in welding of rails, processes are in use at the present time where these hair cracks are easily eliminated. If the work is properly done, satisfactory results are obtained. If it is not done properly, trouble results.

I believe experience will show that although, as pointed out, you have a weak spot at the welded point in the rail, when the welding is properly done, the weakness is not so great as to develop trouble.

The American Society of Mechanical Engineers has prepared a Boiler Code and this Boiler Code does not permit the use of electric welding to so great an extent as we who are interested in pushing electric welding would like. Electric welding is permitted on some types of pressure vessels but at the present time electric welding is not used on pressure vessels used in boilers.

The American Welding Society has a committee making extensive preparations to test a large number of pressure vessels at the Bureau of Standards to get complete information so that the Boiler Code Committee can feel justified in giving more liberal allowances for electric welding.

At the present time steam boilers are not allowed to be welded by the electric welding process. The queer part of it is that the railroads have been repairing locomotive boilers for years and these boiler repairs made on locomotives are on pressures of 200 to 250 lb. Years of experience in locomotive boilers have shown that method must be used. If you please, from a commercial standpoint, the railroads can't get along without it.

While there has been some trouble from improperly made welds on electric locomotives, the process is in use quite generally and I don't think there is any doubt that it will be used more generally in the future. But to answer the question specifically at the present time, pressure vessels—fired pressure vessels—are not allowed to be electrically welded.

Electrochemistry and Electrometallurgy

Annual Report of the Committee on Electrochemistry and Electrometallurgy*

To the Board of Directors:

The Committee on Electrochemistry and Electrometallurgy makes its annual report as follows:

About two years ago, this committee brought to the attention of the Standards Committee the desirability of revising the Institute Standards for storage batteries. A special working committee was then appointed to undertake this task and a tentative standard has been formulated defining the terms and conditions which characterize the rating and behavior of storage batteries. This report is now in the hands of the Standards Committee. It is believed that the work accomplished at the suggestion of this committee will be of value to the storage battery industry, which is an important unit in the electrochemical field.

Standards for the international electrical units are again receiving much attention at the various national standardizing laboratories. These fundamental standards which furnish a basis of measurement for both the physicist and the electrical engineer fall within the field of electrochemistry. Seventeen years have elapsed since the International Technical Committee met in Washington to carry out a joint investigation on the silver voltammeter and the standard cell. At the conclusion of its work the value 1.0183 international volts at 20 deg. cent. was adopted for the Weston Normal cell, and by international agreement, this value became effective on January 1, 1911. The various countries, therefore, started out on this date with identical values for the international volt, which, together with standards of resistance, served to fix the measurement of current, also. Since that time, the basis of reference has been carried forward by means of groups of standard cells and resistances. It is a matter of importance, therefore, that we should determine how accurately these standards have been maintained. Several new groups of standard cells have recently been prepared at the Bureau of Standards, which indicate a very close agreement with the Bureau's existing basis of reference. The results obtained, so far, cannot be considered as conclusive but indicate that our standard for voltage has been maintained over a long period within a few millionths of a volt. Comparisons have also been made with the standards of several other countries and reasonably close agreement has been found in most cases. The necessity still remains, however, for checking the standard for the international volt by means of the silver voltammeter and by the absolute current balance for the measurement of current. Progress is being made in absolute measurement of resistance. As pointed out in last year's report, it is apparent that a considerable difference exists between the international ohm and the absolute ohm.

In reviewing the progress during any particular year, it is always difficult to evaluate the definite advances within so limited a period. New methods, when first tried, are experimental and it is impossible to say whether or not they constitute an advance. Development in electrochemistry and electrometallurgy as well as in other lines is necessarily gradual. It is possible, however, to mention certain developments which appear to distinguish the past year as one of considerable progress in this field.

The introduction of the high-frequency furnace into electric steel foundries is a notable step. The high-frequency furnace has been regarded in the past as a laboratory instrument but now it is rapidly finding favor in the industry as a whole.

Arc furnaces have increased in size and power input largely as a result of the development of three-voltage switching. The principle of this development is based upon the fact that the cold charge within the furnace is capable of absorbing heat at a higher rate than after the charge has become molten. It is possible, therefore, to supply energy very rapidly at the beginning and decrease this as the charge is melted. In the final step, only enough energy is supplied to meet the furnace losses and whatever may be required for chemical reactions during the slagging period. It has been stated that nearly all of the large electric steel-melting installations made during the past year have utilized this principle.

The trend of electric furnace development, however, differs somewhat from that during the period of the World War. The economic limitations to its application are recognized, and the electric furnace is being used now in processes where quality of product is of importance. In this respect, it has been largely responsible for the rapid development in high grade alloys and tool steels. American manufacturers are still importing special steels and pure iron that should be produced here. According to recent reports, a great research campaign on steel is being instituted by one of the large manufacturers.

The advance in the application of electric furnaces in the steel and brass industries has been pointed out in papers presented at the 25th Anniversary Meeting of

*Committee on Electrochemistry and Electrometallurgy:

the Electrochemical Society. The electric steel industry began in this country about 1909, with a half-dozen furnaces producing 13,000 tons. Since then the number of furnaces has increased to over 500 and the product for 1925 was in excess of 600,000 tons. The proportion of electrically melted metal is much greater in the brass industry than in the steel industry. About 625 electric furnaces for brass melting are in use in the United States and Canada. It has been estimated that they used $3,000,000 worth of electrical energy in 1926. A notable saving of fuel compared with that which would have been used in fuel-fired furnaces was accomplished. A still greater economy was achieved by saving over 13,000 tons of metal valued at $2,500,000, which would have been lost in the fuel-fired furnaces.

Comprehensive studies of electric heating are being made by some power companies with a view to analyzing the load possibilities within surrounding territory. In connection with one of these surveys it is interesting to note that a rather definite line of demarcation between ovens and furnaces is made at the temperature of 1000 deg. fahr. Immersion types of electrical heating units are being utilized in existing fuel-fired, stereotype pots having capacities up to six tons.

The use of chromium, both as an electrodeposit and in certain alloys, again occupies a prominent part in the development of electrochemical industry. The previous predictions regarding the usefulness of chromium plating have been largely verified. At present, chromium plating is being applied successfully in the automobile industry, especially on such parts as radiator shells, where its hardness, high luster, and freedom from tarnish are advantageous. It is being used on gages because of its extreme hardness and resistance to abrasion. It is also being applied to plumbing supplies and to a great variety of metal products where good appearance and durability are desirable. The chief obstacle to the more general adoption of chromium plating is the poor "throwing power" that renders difficult the plating of recessed articles. Experience and mechanical ingenuity have frequently led, however, to the successful plating of rather irregular shapes.

A chromium surface affords a valuable protection to steel against corrosion as well as furnishing a high lustrous finish. It is unique in being particularly resistant to the action of sulphur compounds such as seriously impair silvered and other polished metal articles. Large molds for automobile tires, stills used in oil refining, and plates for engraving bank notes are all examples of articles whose life has been greatly extended by the use of chromium plating.

A method has been worked out for producing an exceedingly smooth chromium plating on mirror surfaces. The reflecting power of chromium is not as high as that of silver, but may perhaps be improved by plating with other metals. It is probable that a high average reflecting power of a chromium surface can be maintained over a long period of time, since the chromium surface is not subject to tarnish, discoloration, or scratching from cleaning operations. From the military standpoint, there is considerable advantage in a chromium plated mirror for search lights since such a mirror is free from shattering, if struck by a bullet, and it is better adapted to withstand the high temperature of the arc.

The use of chromium in iron and steel alloys has created widespread interest. There is a variety of these alloys and the properties depend upon the composition, as might readily be supposed. Up to 5 per cent of chromium, high strength, ductility, and hardness are obtained in the presence of at least one other element as, for example, nickel. Higher percentages of chromium impart notable resistance to oxidation, even at high temperatures. Above 20 per cent of chromium, the steels have in addition to oxidation resistance a marked resistance to the action of nitric acid and nitrates.

There have been few marked developments in the process of electrodepositing other metals than chromium, but there has been an increased interest in the theory and mechanism of making such deposits. Commercial processes are being conducted more and more on a scientific basis and it is interesting to find that the application of the hydrogen electrode to the control of refining and plating solutions is teaching the workers to understand the significance of the pH values of their solutions and how these may be used as a guide in the control of their product.

An industrial achievement during the past year has been the commercial development of the electrodeposition of rubber. Rubber is deposited anodically. Rubber deposits can be made quickly in forms corresponding to the shape of the anode. It is reported that wire can be insulated by passing it through the latex solution, the wire serving as the anode and the rubber being deposited on the wire as it passes through. The rubber on the wire then passes through a vulcanizer for the completion of the process.

The development of power devices for use with radio sets has been a matter of interest and concern to battery manufacturers. It seems probable that the inroads of such devices have been more in the field of storage batteries than in the field of dry cells. From the standpoint of the power company, it is interesting to estimate the electrical energy consumed by the use of some of these devices. Recent calculations have shown that a device operating a radio set of five tubes and charging a small storage battery when the set was not in use for a period of approximately 18 hr. per day, required one kilowatt-hour in each 24 hr. Charges for power in this particular case were estimated at $1.80 per month which, in view of the possible use of a large number of such devices, indicate a considerable revenue to be derived from them.

The development of small rectifiers has been stimulated by the growth of the radio industry. The life

and efficiency of the aluminum rectifier has been materially increased. The use of tantalum has been extended not only to the radio field but to other important uses, as in railway signalling. So-called electronic rectifiers, including those having elements of copper oxide and copper sulphide, have become available commercially during the past few months. Such rectifiers are, however, subject to the limitation of a relatively low voltage across each element. They have not been in use for a sufficiently long time to obtain definite data as to their life but it seems likely that they will become of increasing importance. Alloys high in silicon are also being used as valve metals in electrolytic rectifiers.

The development of the Hoopes process for the preparation of a very pure aluminum, was described two years ago. This aluminum, which possesses somewhat different physical and chemical properties from those associated with the ordinary aluminum, is finding commercial use in collapsible tubes and also in metallurgical work where the aluminum may be studied unhampered by the presence of detrimental impurities. Remarkable results in heat-treated castings of the pure metal have been reported. New uses for this material are still being sought. There has been a large increase in the consumption of aluminum alloys, particularly that known as duralumin. Among the novel uses for these alloys may be mentioned the manufacture of aluminum furniture. The attractive finishes in browns, reds, and greens, together with the light weight, have been important factors in promoting the sale of this material.

In the field of rare metals the electrolytic production of pure beryllium may be noted. Some investigation has been made of alloys of aluminum and beryllium but as yet there is no definite information to show whether these will be commercially valuable. Pure thorium is also being made by electrolytic methods. The use of thorium has arisen from its exceptional thermionic properties. Amounts of vanadium sufficiently large for careful experimental investigation have also been produced.

The highly sensitive potassium photoelectric cell has largely displaced the selenium cell. The potassium cell possesses extreme sensitivity and responds instantly to a beam of light. Among the many possible applications for such a cell may be mentioned a recently developed method for television.

At the Anniversary Meeting of the American Electrochemical Society, held in Philadelphia at the close of the month of April, a number of interesting papers was presented reviewing the progress of electrochemistry during the 25 years since the society was founded. One session at this meeting was devoted to the electrochemistry of concentrated solutions. A new theory is rapidly setting aside the old theory of Arrhenius, and Professor Peter Debye, of the University of Zurich, one of the chief exponents of this new theory, was present to present his views. The interest in this matter is shown by the fact that a similar symposium was held at almost the same time by the Faraday Society in England. Industrial engineers found papers of interest in the session devoted to gaseous reduction of ores. Gaseous reduction of iron ores, followed by electric melting of sponge iron, may open up a further field for electrothermics.

The fall meeting of the Electrochemical Society is expected to take the form of a trip through the northwestern part of the United States with stops at numerous points of electrochemical and electrometallurgical interest. Such a trip should result in a better understanding of the work that is being done in this important region and at the same time focus the attention of electrochemists and electrical engineers on the power requirements and possibilities of this region.

The committee wishes to acknowledge with thanks the cooperation of Dr. William Blum, Dr. Colin G. Fink, and Dr. H. W. Gillett, members of the Electrochemical Society, who have furnished valuable information used in preparing this report.

GEORGE W. VINAL, *Chairman*

The Holtwood Steam Plant

Design and Operation in Coordination With Water Power

BY F. A. ALLNER[1]

Member, A. I. E. E.

Synopsis. *The Holtwood Steam Plant is located in Lancaster County, Pa., on the Susquehanna River, about 24 miles above tidewater, adjacent to and closely coordinated with the 111,000-kw. hydroelectric plant of the Pennsylvania Water & Power Company, and through the latter company's customers, it is a part of a hydro-steam system including Baltimore, Md., and Lancaster, York, and Coatesville, Pa., with a total installed generator capacity of about 370,000 kw. and with high-tension connections to two other large systems. It is a pulverized fuel burning station, containing at present two 10,000-kw. generators and three 1400-hp. boilers. The plant is laid out for an ultimate capacity of at least 120,000 kw.*

The station went into operation in July 1925. The paper gives the reasons for building a steam plant at Holtwood, some of them being general advantages in such a location for a plant, which is supplementary to a run-of-river hydroelectric plant, and others being the particular advantage, in this instance. In general, during the low-flow period, the steam plant carries the base load or belt generation, and during high flow, when the hydroelectric plant is operated at maximum capacity whenever the load permits, the steam plant carries the peaks. This station was especially planned to suit such conditions of operation and was designed for mechanical sturdiness, reliability of service, quick starting, ability to float in at no load, and for maximum coordination with the hydroelectric plant rather than for maximum economy or minimum first cost. A number of special features incorporated to carry out this aim is described in the paper, among them being arrangements to facilitate quick starting and floating in, and a special governor so constructed that the speed regulation may be changed by remote control while the unit is running. A comparative analysis of starting times of hydroelectric and steam units at Holtwood is given, showing that in spite of special design, the steam unit requires a much longer time than the hydroelectric unit.

The pulverized fuel process was adopted in order to secure better sustained efficiency over a wide range of boiler rating, to reduce banking losses, and because it was desired to burn bituminous coal of various grades in the same furnaces with river bottom anthracite coal which is dredged from the upper end of the pond formed by the Holtwood dam. This has been successfully accomplished, approximately one-third of all the coal burned, so far, having been river anthracite. During short periods, anthracite alone has been burned, but most of the time the two kinds of coal are mixed before being dried and pulverized. Maintenance costs at the pulverizing plant when burning 100 per cent anthracite are very high.

Data are presented showing the first cost of the plant, fuel rates, costs of preparing river anthracite, outage time of the generating units, and other operating results. A brief summary is given also of minor difficulties.

On account of the unusual operating requirements as to loading, fuel supply, etc., the design and operation of this plant involved a number of interesting problems in design and operation, for the solution of which only a limited amount of experience was available. It is believed that nearly all of the major problems have been solved satisfactorily, but there is still need for further experimentation to secure the best possible results from the equipment installed.

Brief Description of System

THE Pennsylvania Water & Power Company is a generating and transmission company, selling power at wholesale to public utilities. Its system consists of a combined hydroelectric and steam power development at Holtwood, Pa., on the Susquehanna River about 10 miles (16.1 km) above the Pennsylvania-Maryland state line, with high-tension steel tower lines radiating like the spokes of a wheel (Fig. 1) to Baltimore, Md. 40 mil. (64.4 km.) distant; Lancaster, Pa., 14 mi. (22.5 km.); York, Pa., 23 mi. (37.0 km.); and Coatesville, Pa., 30 mi. (48.3 km.).

The Holtwood (formerly called the McCalls Ferry) hydroelectric development (Fig. 2) is a low-head run-of-river plant with a weighted average head under present conditions of about 52 ft. (15.8 m.). The first unit went into operation in October 1910 and after the initial five unit installation the plant was extended in several successive steps, reaching its present rated generator capacity of 111,000 kw. early in 1924. The rated capacity of the waterwheels varies from 13,500 hp. for the older type of double-runner turbines to 20,000 hp. for the latest single-runner type. The first eight units are 25-cycle, this frequency having been adopted to meet the requirements of Baltimore and Lancaster. The last two units installed in 1923-1924 are 60-cycle to meet the needs of York and Coatesville and what is now the larger and rapidly growing part of the Lancaster load, which is supplied over a 60-cycle line built in 1924. The 25- and 60-cycle systems can be tied together by a total capacity of 25,000 kw. in seven synchronous frequency changers, of which two 5000-kw. sets are located at the hydroelectric plant, and the balance of 15,000 kw. at Lancaster. The latter equipment was formerly used for supplying the 60-cycle load in that city when only two 25-cycle circuits were available from Holtwood.

The normal full-load discharge of the hydroelectric plant is now about 30,000 cubic ft. (850 cu. m.) per sec. with a maximum under favorable hydraulic conditions of 31,500 (892 cu. m. per sec.). The former flow is available in the average year 41 per cent of the time. The flow of the Susquehanna is unusually variable. The lowest 24 hr. flow recorded at Holtwood since the plant went into operation in 1910 (from which time more reliable flow measurements are available than had theretofore existed) was 3200 cu. ft. per sec. (90.7 cu. m. per sec.), and the lowest

1. General Superintendent, Pennsylvania Water & Power Co., Baltimore, Md.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

seven day average was 3600 cu. ft. per sec. (102 cu. m. per sec.); the maximum 24-hr. flow was 441,000 cu. ft. per sec. (12,470 cu. m. per sec.).

The pond or reservoir formed by the Holtwood dam has an area of about four sq. mi. and a draw-down capacity of approximately 800,000,000 cu. ft. (22,700,000 cu. m.). Under present conditions of system load demands this drawdown gives complete weekly pondage to effectually equalize differences in daily flow and shape of load curve up to an average weekly river stage of 4200 cu. ft. per sec. (119 cu. m. per sec.). The term "complete" pondage means that if the hydroelectric plant carries the entire system load above a certain base steam line, and the forebay on Friday evening is brought to a point not below the desired minimum level, the pond will just fill up again by Monday morning without spilling. In other words, the inflow of the river between Friday evening and Monday morning, minus whatever is used for a small amount of generation during that period, will be discharged during the period from Monday morning to Friday evening, in addition to the inflow of the river on these five days.

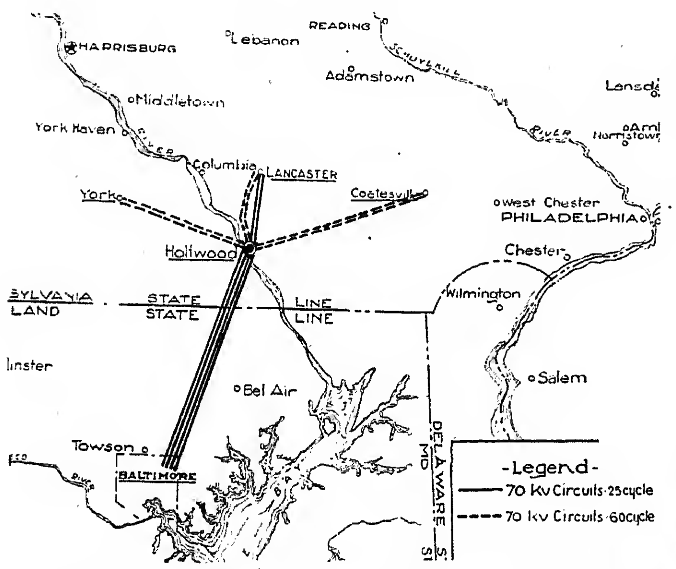

Fig. 1—Map of Holtwood Transmission System

With an average weekly flow of 4200 cu. ft. per sec. (119 cu. m. per sec.) the average five day draft can be increased by 1800 cu. ft. per sec. (51 cu. m. per sec.), to approximately 6000 cu. ft. per sec. (170 cu. m. per sec.); but with an average weekly flow of only 3600 cu. ft. per sec. (102 cu. m. per sec.), the effective five day average draft can be raised to only about 5200 cu. ft. per sec. (147 cu. m. per sec.), because the inflow at the rate of 3600 cu. ft. per sec. is not sufficient to completely refill the pond after maximum draw down as in the case of 4200 cu. ft per sec. inflow. For average weekly flows in excess of 4200 cu. ft. per sec. the increase in the daily discharge on the five week days will be limited to approximately 1800 cu. ft. per sec. on account of the minimum desired forebay level at the time of maximum drawdown, and the inflow over the weekend will be more than sufficient to completely refill the pond before Monday morning.

The installed capacity of the Baltimore steam plants of the Consolidated Gas, Electric Light & Power Company is about 220,000 kw. At Lancaster the Edison Electric Company has a standby steam plant with rated generator capacity of 7000 kw. At York, the Edison Light & Power Company has a steam generating station of 8500 kw. capacity and a tie-in connection of 7500 kw. with the large hydro-steam system of the Metropolitan Edison Company, from which it receives approximately one-half of its load requirements. At Coatesville, the Chester Valley Electric Company has a steam plant of a rated capacity slightly in excess of 3000 kw. and also a 5000-kw. tie-in connection with the Philadelphia Suburban Gas & Electric Company.

General System Operation

The method of operating the system for maximum coordination of waterpower and steam has been explained in a previous paper[2] and will not be discussed in detail here. Generally speaking, during high or excess flow the aim is to deliver the maximum amount of energy from the river. As long as there is water wasted over the dam, hydraulic efficiency is of no importance. The hydroelectric units are operated at full load as

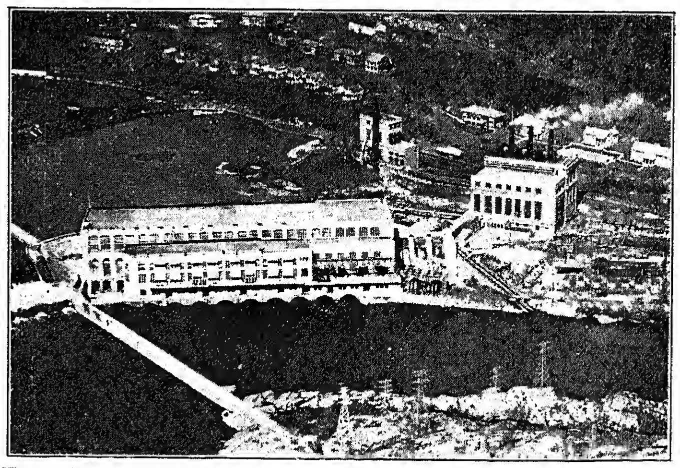

Fig. 2—View of Holtwood Water Power Plant and Steam Station

long as possible and carry as much of the system load as is practicable when this is less than the hydroelectric capacity. The steam plants then operate "on the peaks" and carry all swings. In low or deficient flow, conditions are reversed. The steam plants are given the base load or belt generation and the hydroelectric plant operates "on the peaks," and takes care of load fluctuations during the hour, even though such operation under average low-flow conditions causes an energy loss of about 7 per cent, and at very low river stages as much as 15 per cent, compared with 100 per cent load factor,

2. A. S. M. E. *Transactions*, 1925, p. 379.

belt load generation. These differences are due more to the large hydraulic gradient of the tailrace than to the carrying of swings and the uneconomical loading of individual units.

Under normal conditions the pond is drawn upon only to the extent of compensating for daily and week-end fluctuations in inflow and load demand and restoration of maximum pond level is aimed at on the morning of every week day. Thus the maximum practical amount of pondage is held in reserve to meet major emergency conditions or temporary outages at the steam plants.

REASONS FOR BUILDING THE HOLTWOOD STEAM PLANT

Until recently the Power Company depended entirely upon its customers' steam plants for makeup steam generation. The company's contracts give it the right to call on any of the steam plants previously listed for generation under certain conditions. In 1925, however, the company, through a subsidiary, the Holtwood Power Company, built a steam plant at Holtwood. Additional steam capacity was required for the system. The Consolidated Gas, Electric Light & Power Company of Baltimore was ready to proceed with its new Gould Street plant, but after careful joint study it was decided that Holtwood was the logical place for the next step in steam station construction and arrangements were made with the Baltimore company to temporarily postpone the Gould Street project. The principal reasons for this decision were as follows:

1. The 60-cycle load in Pennsylvania was increasing rapidly and additional capacity was essential. None of the Pennsylvania customers' steam plants is modern and well adapted for economical extension, and existing power agreements did not provide for the use of more than the capacity available at the time when Holtwood supply had started.

2. The transmission of primary power from Baltimore to the Pennsylvania 60-cycle system to take care of the growth of the Power Company's load commitments, would have required additional frequency changers at Holtwood, with consequent conversion losses in addition to increased transmission losses. A direct connection of the Baltimore 62½-cycle system with the 60-cycle system in Pennsylvania was not possible without extensive changes in Baltimore.

3. A plant at Holtwood, being at the hub of the wheel, so to speak, could offer the maximum protection to all of the radial lines. The transmission of power from any customer city to Holtwood and thence to another city requires a reversal of flow, with consequent complication of voltage regulation. From this point of view the logical place for a steam plant supplementary to hydro is at the water-power site.

4. Since the Lancaster dual frequency supply had grown to about 25,000 kw. it was desired to always maintain two sources of supply, which during very low river stages required an appreciable amount of 60-cycle hydroelectric generation during off-peak hours. Sixty-cycle supply from the Holtwood steam plant enabled the system to conserve the entire hydroelectric energy exclusively for peak service, thus indirectly gaining ineffective peak supply for the system appreciably more than the steam capacity proper.

5. There are large deposits of river bottom anthracite coal in the Holtwood pond. The location of a steam plant at Holtwood made it possible to use some of this coal and store same eventually in very large quantities, thus providing a more economical and effective emergency insurance of fuel supply than is practical with bituminous coal at the city stations.

6. The installation of a steam plant adjacent to a variable flow run-of-river hydroelectric plant makes it possible to effect considerable savings in operating expense through the coordination of operation and maintenance work. In such a system so far as possible, all maintenance work at the hydroelectric plant is done during low flow, whereas repairs at the steam plant are concentrated in the high-flow period. This makes it possible for the same force, at least in part, to be used at both plants.

BRIEF DESCRIPTION OF STEAM PLANT (FIGS. 3 & 4)

It is not the purpose of this paper to give a detailed description of the entire plant and an itemized list of equipment. However, the principal physical characteristics will be mentioned as a ground work for a discussion of special features and of the reasons for making certain decisions.

The generating equipment proper consists of two

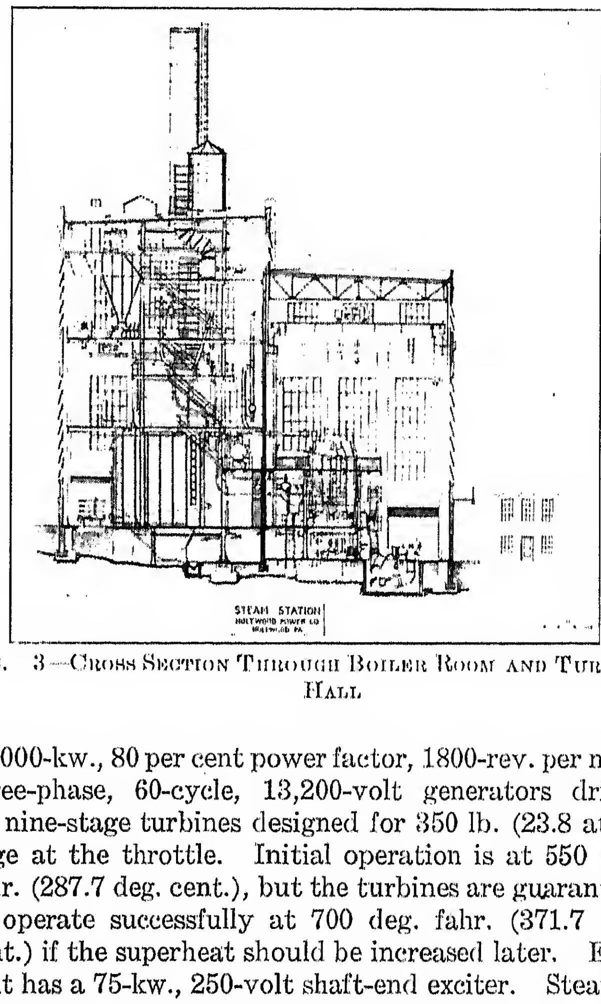

FIG. 3—CROSS SECTION THROUGH BOILER ROOM AND TURBINE HALL

10,000-kw., 80 per cent power factor, 1800-rev. per min., three-phase, 60-cycle, 13,200-volt generators driven by nine-stage turbines designed for 350 lb. (23.8 atm.) gage at the throttle. Initial operation is at 550 deg. fahr. (287.7 deg. cent.), but the turbines are guaranteed to operate successfully at 700 deg. fahr. (371.7 deg. cent.) if the superheat should be increased later. Each unit has a 75-kw., 250-volt shaft-end exciter. Steam is bled from the turbines at three stages—the third, fifth, and seventh. Each turbo generator is equipped with a 13,000 sq. ft. (1208 sq. m.) single pass condenser.

The boiler installation consists of three cross drum vertically baffled three-pass B. & W. boilers, each with a heating surface of 14,056 sq. ft., (1305.7 sq. m.), exclusive of the water screen at the bottom and back of the furnace which has an additional surface of 775 sq. ft. (72.0 sq. m.). The working pressure is 385 lb.

(26.2 atm.) gage. Each boiler is equipped with a convection type superheater above the top row of water tubes, designed to give a steam temperature of 560 deg. fahr. (293.3 deg. cent.) at 250 per cent rating. Each boiler has its own stack with a height of 126 ft. (38.4 m.) above the burners. There are two induced draft fans above each boiler. Neither economizers nor air preheaters are installed, although provision is made to add such equipment later on, if found advisable. Makeup water is furnished by two horizontal single effect evaporators which are supplied with filtered river water.

The furnaces have air-cooled side and front walls. Each furnace has a volume of 11,500 cu. ft. (325 cu. m.) above the water screen. The vertical burners, of which there are eight to a boiler, are set under the high end of the boiler. Pulverized coal feeders are arranged in four motor-driven pairs per boiler. There are three primary air fans. The boilers are arranged in a single row parallel to the turbine hall, in which the turbines are placed lengthwise. The boilers and furnaces are guaranteed to give 300 per cent rating for twenty-four hr. or 400 per cent for twelve hr. when using bituminous coal, and 250 per cent for 24 hr. or 325 per cent for 12 hr. using river anthracite.

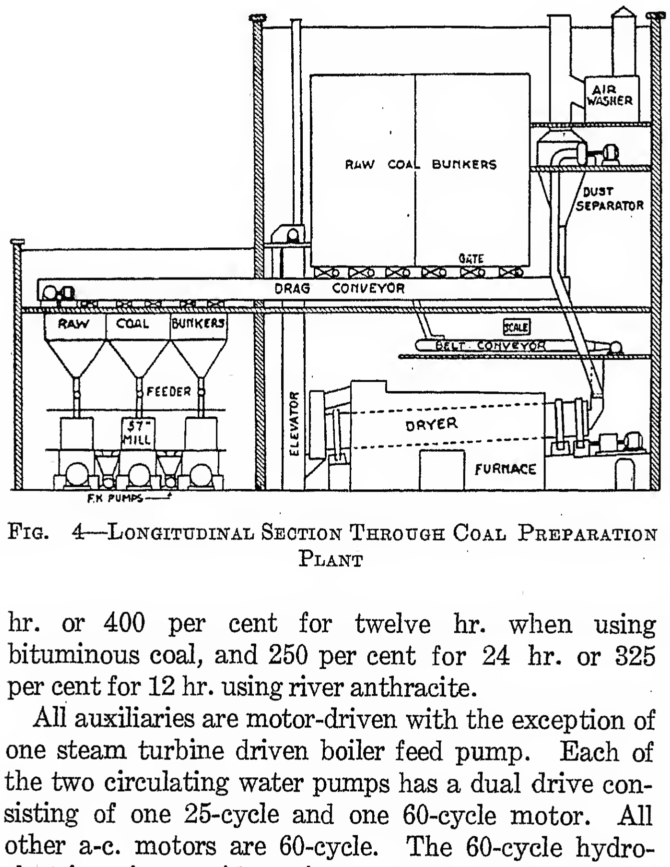

FIG. 4—LONGITUDINAL SECTION THROUGH COAL PREPARATION PLANT

All auxiliaries are motor-driven with the exception of one steam turbine driven boiler feed pump. Each of the two circulating water pumps has a dual drive consisting of one 25-cycle and one 60-cycle motor. All other a-c. motors are 60-cycle. The 60-cycle hydroelectric units provide an independent source of power, which is considered of greater reliability than shaft-end auxiliary generators or house turbines. The boilers and furnaces are equipped with Bailey automatic combustion controls which operate the coal feeders, the induced draft fans, and the stack dampers.

The coal preparation plant occupies a separate building located upstream from the boiler house. At the top of the building there are two raw coal bins with a total capacity of 1000 tons to which coal is elevated by a skip hoist. From the raw coal bunkers coal is fed by a drag conveyer to a 6½-ft. by 50-ft. (1.98 m. by 15.2 m.) rotary dryer with a capacity of 25 net tons of bituminous or 24 net tons of river anthracite coal per hr. There are three dry coal bins each with a capacity of 20 net tons. The pulverizing equipment consists of three Fuller 57 in. (1.45 m.) screen type mills, each with a guaranteed capacity of 7½ net tons per hr. of bituminous or 4½ net tons of river coal when grinding to a fineness of 83 to 87 per cent through a 200 mesh screen. Pulverized coal is pumped to the boiler house by two Fuller-Kinyon pumps through two five-in. pipe lines with a horizontal length of about 350 ft. (106.7 m.) and a vertical rise of 85 ft. (25.9 m.).

Bituminous coal is received by railroad car and dumped into a track hopper mounted over a crusher. River coal is for the most part scowed to the forebay ramp where it is transferred to a railroad car and hauled to the track hopper.

At present the coal storage facilities consist of a drag scraper storage yard with a capacity of about 10,000 tons. Coal is also stocked out and reclaimed by locomotive crane from several areas adjacent to railroad sidings. With the increase in plant capacity the main storage will be gradually extended by filling in a large shallow area of the forebay.

CONTROLLING FACTORS AND SPECIAL FEATURES OF DESIGN

The Holtwood plant was designed not so much for maximum economy or minimum first cost, but primarily for mechanical sturdiness, reliability of service, quick starting, ability to float in at no-load, and for facilitating the proper division of load between hydroelectric and steam plants. In carrying out these aims a number of interesting questions arose and several special features were incorporated which will be discussed below.

Choice of Site. The forebay of the hydroelectric plant, which is protected from floating ice and debris by a rock fill ramp, skimmer wall, and floating booms, offered an ideal source for circulating water. The exact location of the steam plant, however, presented an interesting problem. The site finally selected for the initial section of the power house was immediately below (*i. e.*, on the downstream side) and abutting on the wing wall from the river shore to the hydroelectric plant. Circulating water for the condensers is taken from the forebay and returned to the gate house of the hydroelectric plant, the tunnels having been cut through the wing wall.

Serious consideration was given to a site along the tailrace below the hydroelectric plant. The natural head from forebay to tailrace would then have been used for discharging water through the condensers, thus doing away with pumping equipment. This

scheme looked particularly attractive from the point of view of saving a few minutes in the starting operation. The head, however, is considerably greater than that required to overcome the frictional resistance of the condensers and water conduits. Supplementary to this scheme, a plan was also considered of using the excess head to drive auxiliary hydraulic turbines, but this was an added complication.

As the heaviest steam generation and maximum draft of circulating water would be at times of very low flow, the use of water in this manner would reduce the hydroelectric plant output during these low river stages. During the high-flow period there would be a gain in the combined net output of the hydro and steam plants. If arrangements were made to utilize the excess head beyond the condensers, and if the hydroelectric plant operated 24 hr. a day as during moderate low flow, the reduction in hydroelectric plant output would be less than the equivalent amount of electrical energy consumed in the motors. However, in very low flow the hydroelectric plant shuts down at night and all the available hydroelectric energy is thrown in on the peaks. The diversion of water through the condensers during the 24 hr. of steam operation would still show a net gain in energy output, but would cause an appreciable reduction in the peak service rendered by the hydroelectric plant on account of the concentration of all the hydroelectric energy during the short period of peak generation. Maximum peak service in very low flow is of prime importance, particularly as there is a tendency for the peak service corresponding to a certain amount of hydroelectric energy to increase from year to year with the growth of the system load.

Perhaps the greatest advantage of the site selected was the greater amount of space available. The plant is laid out for six turbine bays and its ultimate capacity will be approximately 120,000 kw. The future extensions will be made to the north of the wing wall into a shallow portion of the forebay area where little cofferdamming will be required. The initial two-bay section of the power house was built entirely in the dry, the wing wall acting as a bulkhead.

Another advantage of the layout adopted is that the injection of warm condenser discharge into the end of the gate house is of value in reducing the chances of capacity reductions caused by frazil ice on the hydroelectric units at that end of the power house. It has been calculated that for the completed plant, enough heat would be discharged in the condenser water to raise the temperature of all the water entering the hydro units, if perfectly mixed with it, by nearly 0.2 deg. fahr. (0.11 deg. cent.) exclusive of the heat required to melt the ice. Experts on ice have declared that a rise of less than 0.01 deg. fahr. (0.0055 deg. cent.) may be enough to remove the "stickiness" of frazil ice.

Centralized Control. Electrically speaking, the steam plant is essentially a part of the 60-cycle section of the hydroelectric plant. The steam generator leads are carried through a cable duct to oil switches located in the hydroelectric plant switchroom. The control panels for the steam units are a part of the 60-cycle switchboard in the hydroelectric plant. The Tirrill element and the controls for the Keilholtz-Ricketts booster regulator used on the steam units are located on this switchboard.

Size and Type of Generating Units. From the point of view of low first cost and of economy of operation, under base load conditions, larger generating units would have been desirable. However, as previously stated, these considerations were subordinated to sturdiness, reliability of service, quick starting, and maximum coordination with the hydroelectric plant. Furthermore, under the existing conditions, these initial steam units must often operate at a comparatively small load, either when separated from the rest of the generating system or in high flow when operating on the peaks so as to "skim off" the top of the load and give the hydroelectric units maximum load. All of these considerations pointed toward relatively small sturdy units for the initial installation, approximating in capacity the hydroelectric units.

Auxiliary Power System. The number of oil circuit breakers on the auxiliary power system has been kept to a minimum. Magnetic contactors have been employed for all switching purposes, except on main feeders between distribution boards. Tests were made on different types of contactors to determine their ability to rupture the maximum expected short circuits. The control for contactors on essential auxiliaries is so arranged that either a contactor will not open on low-voltage, or will immediately reclose on restoration of voltage.

Special precautions to avoid explosion hazard have been taken in the installation of the electrical system; in the coal preparation plant, distribution switchboard and contactors for the main auxiliaries are located in a special switchroom, isolated from the main building by concrete fire walls. All push buttons, and such manual controllers as are necessary in the mill and dryer rooms, are of the Navy standard vaporproof type. All lighting fixtures are dust proof and vaporproof.

Quick Starting of Hydroelectric and Steam Units. In a hydroelectric system in high flow, when the system load is less than the hydroelectric capacity the steam plant should be shut down at night and theoretically should not operate in the morning until the load becomes equal to the hydroelectric capacity, when it should pick up that portion of the load over and above the hydroelectric capacity. Modern steam turbines designed with small clearances and operating at high temperatures require normally approximately one hour for starting. This, of course, entails the use of steam before it is really required. If it is desired always to have spare steam capacity available for immediate

use in the event of breakdowns, it is necessary to operate normally a larger number of units than would be required for most economical generation.

Hydraulic turbines operating at low or medium heads or having only short penstocks are inherently quick starting machines. Temperature differences are practically nil, clearances are relatively large, and construction is sturdy. The starting time can be further reduced by special arrangement of control valves and instruments, by automatic starting of pumps supplying the pressure

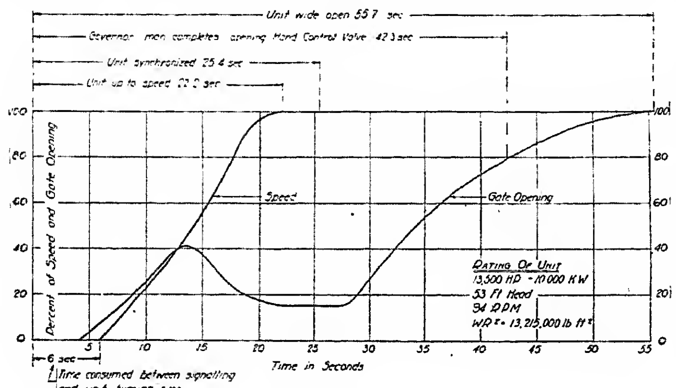

FIG. 5—ANALYSIS OF TIME CONSUMED IN STARTING A 10,000-KW. HYDRO UNIT

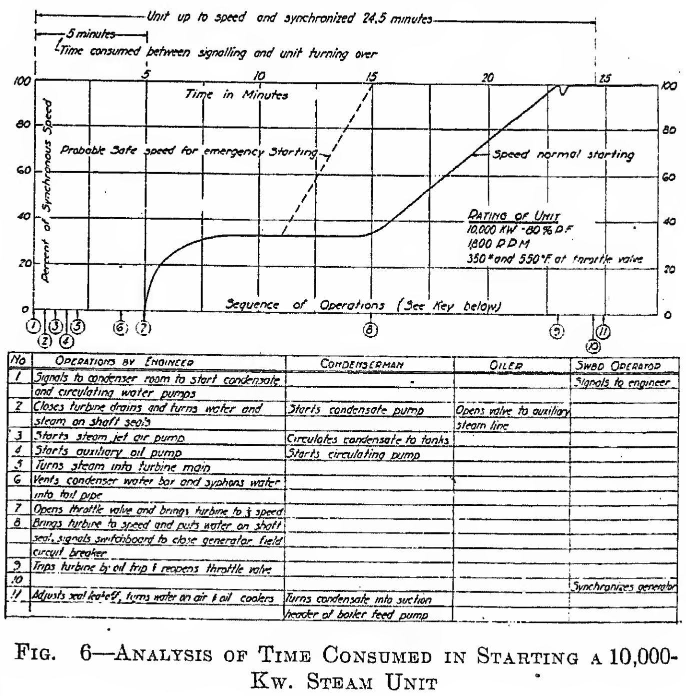
fluid of servo motors, etc., and by training the operators. At the Holtwood hydroelectric plant any of the 10 units, ranging in capacity from 13,500 to 20,000 hp. is commonly started from standstill without preliminary preparation and synchronized in less than one minute, and frequently in less than half a minute. Fig 5. gives an analysis of the few steps involved in this operation, requiring only two men—the governor man and the switchboard operator. The low-flow standby service of a low-head hydroelectric plant equipped with pondage has well been called "a-c. storage battery service," *i. e.*, its ability to synchronize the entire capacity in a few minutes and maintain full output for several hours or days, and thus tide over temporary emergencies at the steam plants. During the high-flow period this emergency service is not available at the hydroelectric plant, because all hydroelectric units are operating at maximum gate opening.

When going into the field of steam generation at Holtwood, the power company desired to extend so far as practicable this quick starting ability to its steam plant, thus giving to the hydroelectric steam combination a certain amount of quick emergency service also during the high-flow period. This was one of the reasons for selecting a particularly sturdy type of turbine of relatively small size. The specifications provide that "every effort is to be made in the construction of these machines to make them suitable for starting up in the minimum time." Under normal conditions a Holtwood steam unit is paralleled in 25 min. and in emergency the time can be reduced to 15 min. from the time the start signal is given. Fig. 6 gives an analysis of the operation. A total of four men are engaged in this operation and the time consumed and the number of steps required are still in striking contrast to hydroelectric starting.

The desire to facilitate quick starting was the chief reason for limiting the superheat in the initial installation to a total temperature of 550 degrees at the throttle. In future extensions it is planned to install larger units, using the first two for quick starting purposes. At that time radiant type superheaters may be installed, giving a total steam temperature of 725 deg. Various schemes have been proposed for maintaining the quick starting feature on the first units, if and when this step is taken, such as omitting the radiant superheater in one boiler, use of a Ruths accumulator, etc.

Floating In. As a practical matter, in a case such as the above mentioned building up of load, and whenever the load is at or near the hydroelectric capacity, it is necessary to have spare capacity on the bus. At such a time in high flow any load carried by a steam unit causes a net loss of the equivalent amount of water power. It is therefore highly desirable to have steam units able to float in or motor at no load. On the Holtwood units a by-pass is provided around the



No	Operations by Engineer	Condenserman	Oiler	Swbd Operator
1	Signals to condenser room to start condensate and circulating water pumps			Signals to engineer
2	Closes turbine drains and turns water and steam on shaft seals	Starts condensate pump	Opens valve to auxiliary steam line	
3	Starts steam jet air pump	Circulates condensate to tanks		
4	Starts auxiliary oil pump	Starts circulating pump		
5	Turns steam into turbine main			
6	Vents condenser water box and syphons water into tail pipe			
7	Opens throttle valve and brings turbine to ⅓ speed			
8	Brings turbine to speed and puts water on shaft seal, signals switchboard to close generator field circuit breaker			
9	Trips turbine by oil trip & reopens throttle valve			
10				Synchronizes generator
11	Adjusts seal leakoff, turns water on air & oil coolers	Turns condensate into suction header of boiler feed pump		

FIG. 6—ANALYSIS OF TIME CONSUMED IN STARTING A 10,000-KW. STEAM UNIT

main steam control valves to admit enough steam to the turbine to keep it cool. The manufacturers' guarantee provides that with this by-pass connection open "it will be possible to motor the turbine by means of its generator with the control valves shut off a period of one hour without overheating any parts of the turbine."

A ¾-in. (1.9 cm.) orifice is at present installed in the by-pass. It has been found that this discharges enough steam to drive the unit at slightly more than synchronous speed under excitation. This is more than

is necessary for cooling and prevents lowering of speed for synchronizing unless the speed is reduced by manual manipulation of the vacuum or the throttle. Tests are not yet completed to determine the safe minimum size of orifice.

Fig. 7 illustrates the division of load between a 12,000-kw. hydroelectric unit and one of the steam units over the noon hour drop when operating in parallel on the Lancaster 60-cycle load separated from the rest of the system. Until about 11:55 a. m. the hydroelectric unit is "wide open," with the steam turbine taking the momentary swings and the more gradual load changes. When the customer's load drops below the hydroelectric capacity, the hydroelectric governor begins to function or to "maintain the frequency" as the operators say, and the steam unit "floats in" or motors. Occasionally small amounts of power are momentarily supplied by the steam turbine, due to slight decreases in frequency which draw on the kinetic energy stored in the rotor and also in a few cases probably cause the steam

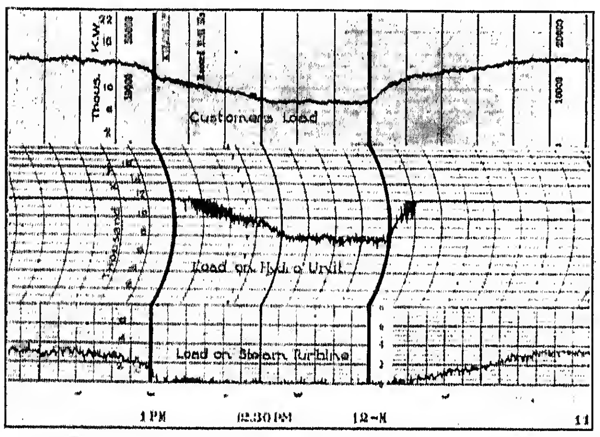


Fig. 7 Wattmeter Charts During Floating-In Period Over the Noon Hour

governor to open a control valve momentarily. The graphic chart of steam turbine output does not show input when momentarily motoring because of a zero stop on the meter.

When the load has increased to the capacity of the hydroelectric unit the conditions prevailing before the noon hour are restored. The boiler operation is approximately as follows: a short time before noon the rate of coal feed is reduced so as to lower the steam sufficiently to avoid "blowing-off" as the load drops. The burner flames are extinguished just before the beginning of the motoring period, but are relighted occasionally as required to maintain the pressure within the desired range.

Special Governors. In order to change the per cent speed regulation on the standard type of governor it is usually necessary to shut down the steam turbine. In a hydroelectric steam system such as has been described, when the steam unit is carrying the base load it is desirable that its regulation should be relatively large, whereas when it is carrying the load fluctuations or peaks and the hydroelectric units are carrying the base load, the steam unit regulation should be relatively small. The Holtwood steam units operate also in parallel with a number of other steam units, where regulation cannot be adjusted while running. In order to control Holtwood steam generation in respect to these other steam stations, either towards assigning to the Holtwood units a steady load or a fluctuating load, it was thought desirable to be able to change from one condition to the other without shutting down the unit. Hence a special motor driven device was installed for changing the governor regulation. This device is controlled from the switchboard in the hydroelectric plant. The specifications provide for an adjustment range from 1 per cent to 5 per cent, although the guaranteed range is only 2 per cent to 5 per cent. Tests made on the governors at the factory showed a range from 1.6 per cent to 7.4 per cent.

The manufacturer's guarantees provide that the characteristics of the governors are such that there will not be any hunting between the steam turbines and the hydro units or between the two steam turbines under either of the two following operating conditions:

1. Steady continuous load carried on waterwheel generators, and fluctuating load carried on the steam turbines.
2. Steady continuous load carried on steam turbines and fluctuating load carried on waterwheel-driven generators.

The guarantees also provide that the speed regulation and the speed of operation of the governor and control mechanism of the turbine will be such that with full load thrown off the generator and the field circuit breaker opened simultaneously, the speed will not exceed that for which the emergency trip is set (the latter is to be not over 110 per cent).

In order to make it possible to restore normal frequency in case of a sudden overload due to the breakdown of a generating unit or other cause, by paralleling a steam unit without cutting off customers' load, a particularly wide range is provided in the governor control of the Holtwood units. The speed can be changed by remote control from 107 per cent or 64 cycles to 85 per cent or 51 cycles, but in the latter case the by-pass around the control valves must be throttled which, as stated previously, is at present too large.

Condensers. The heaviest duty on the steam units falls in the period of very low flow, which usually is also a warm weather period. Also in cold weather, as for example, in case of a frazil ice run, it may be desired to throw the maximum possible overload on a steam unit for a short time. This was the cause of conservatism in condenser design. For ordinary conditions probably a 9000-sq. ft. (836-sq. m.) single-pass condenser would have sufficed, but in line with the policy of insuring a safe margin of capacity and maximum coordination with the hydroelectric plant, even at the expense of first cost, a 13,000-sq. ft. (1208-sq. m.) single pass condenser was installed on each unit. Sustained gross generating capacity for highest water temperature in

December, 38 deg. fahr. (3.3 deg. cent.), was found to be 15,200 kw. limited by the turbine, and for highest water temperatures in September, 75 deg. fahr. (23.9 deg. cent.), 13,200 kw. at 100 per cent power factor, limited by the heating of the generator field.

Pulverized Fuel. The principal reasons for installing a pulverized coal burning plant were as follows:

1. It was believed that during the low-flow period when the steam units would carry heavy base loads as well as during the high-flow period with its fluctuating loads, the pulverized system would have an advantage over stokers in being able to maintain good efficiencies over a wider range of load with varying grades of fuel.
2. It was desired to reduce the starting and banking losses to a minimum. With a stoker-fired plant these would have been particularly great during the high-flow period when the steam plant carries peaks and fluctuations as outlined above.
3. Any known and tried stokers suitable for burning fine sizes of anthracite coal would not have been adapted to the use of eastern bituminous coal. It was believed that it would be possible by adopting the pulverized coal process to prepare and burn either or both types of coal with the same equipment. It will be shown later under operating results that this hope has been fulfilled. The high speed ball type of pulverizing mill was adopted because it is best suited for the preparation of anthracite as well as bituminous coal.
4. Economies could be effected in preparation of coal by utilizing surplus off-peak hydroelectric energy in high flow for operating the pulverizing plant.

Construction and Cost Data

Decision to build the steam plant was made April 2, 1924. The turbo generators were ordered May 23, and excavation began June 24, 1924. The first generat-

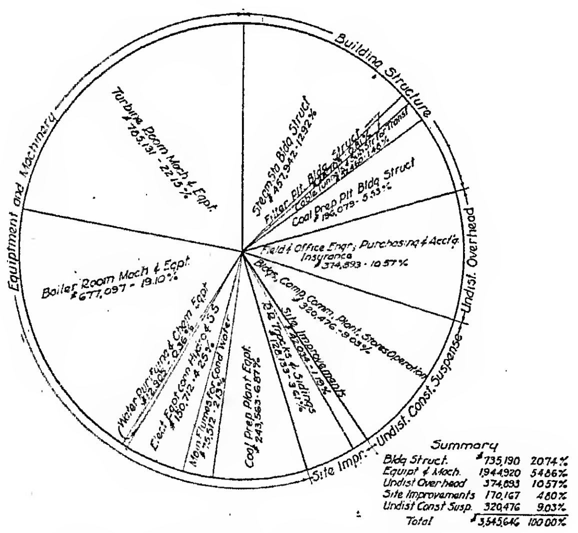

FIG. 8—ANALYSIS OF CONSTRUCTION COSTS

ing unit went into regular commercial operation July 20, 1925, and the second on August 4, 1925.

The design work was carried out by the Consolidated Gas, Electric Light & Power Company of Baltimore. The field engineering and construction work was handled by the power company's own forces.

Fig. 8 is a summary of the cost of the plant, exclusive of property, legal and corporate expenses, housing for employees, interest during construction, and exclusive of any contractors' fees. There are several factors which should be borne in mind in comparing these costs with those of other plants. The present boiler installation is larger than needed for the first two turbines, and surplus pulverizing capacity on a bituminous rating was installed to off-set partially the reduction in capacity when milling river coal. Switching equipment is installed for two more units and the cable tunnel to the hydroelectric plant will take care of the ultimate station. The intake and discharge tunnels are built for two more units of a capacity up to 35,000 kw. each. The width of the power house is sufficient to accommodate units up to 35,000-kw. capacity and larger boilers.

It may be of interest to note that the cost of the preparation plant per net ton of pulverized output per hour on a bituminous rating was $8,720 for structures and $10,830 for equipment, or a total of $19,550.

Operating Results and Experience

General Results. In the calendar year 1926, the gross output of the steam plant was 60,870,000 kw-hr. The station uses, including coal handling and preparation, amounted to 4,200,000 kw-hr., or 6.9 per cent, giving a net generation of 56,670,000 kw-hr. The one-hour peak load was 26,600 kw. or 33 per cent more than the nominal rating of the two units. The annual load factor was 26.1 per cent and the annual capacity factor based on gross generation was 34.8 per cent. The variable character of the plant load is shown by the fact that the highest net output was a little over 10,000,000 kw-hr. in the month of July, whereas the lowest output was only about 2,500,000 kw-hr. in the month of October. The year 1926 was of better than average river flow, which accounts for the relatively low output of the steam plant.

The average economy for the year was 21,160 B. t. u. (5331 kg-cal.) per net kw-hr. The best weekly economy reported was 18,350 B. t. u. (4623 kg-cal.) per net kw-hr. burning 100 per cent bituminous, the best weekly economy burning 100 per cent anthracite was 19,800 B. t. u. (5010 kg-cal.) per net kw-hr. The average boiler and furnace efficiency for the year was 79.6 per cent without allowance for dryer fuel or for energy requirements of the boiler auxiliaries.

The boilers have operated up to 385 per cent rating for a few hours at a time. The average rating for the total steaming period was 201 per cent.

Of the total coal used, 35.4 per cent was river anthracite and 64.6 per cent bituminous.

Of the total coal used, 35.4 per cent was river anthracite and 64.6 per cent bituminous. The average quality of the two fuels was approximately as follows:

	Anthracite	Bituminous
Moisture................	13.0 per cent	3.8 per cent
Ash, dry basis............	16.7 per cent	11.1 per cent
B. t. u. wet basis (kg-cal.)..	10,880 (6,044)	13,210 (7,339)

A great deal of the bituminous coal burned was of an inferior quality with an ash content as high as 20 per cent. Of the total dry ash in river anthracite, about 6½ per cent is intrinsic ash and the rest is foreign matter. Attempts have been made to evaluate various reductions in the latter item but the findings are not yet conclusive. Such reduction in ash means not only higher heating value per pound, decreased power consumption in grinding, and increase in effective plant output, but also a very appreciable reduction in maintenance cost of mills. Mill maintenance is affected particularly by sand, small pebbles, and stones. Several schemes of reducing the ash have been tried in the recovery process of river coal, but they are still in the experimental stage.

Use of River Anthracite. A detailed discussion of the use of river coal does not come within the scope of this paper, but a few outstanding phases of the subject will be mentioned.

Up to date roughly one-third of all the coal burned has been river anthracite. In a few periods aggregating about ten weeks 100 per cent anthracite has been burned. At certain other times the fuel was all bituminous. Between these two extremes various mixtures were tried out. The volatile in river anthracite is so low (averaging a little over 8 per cent) that it is somewhat difficult to ignite and the flame is not as stable as with bituminous. The anthracite coal is ignited by means of flexible hose oil torches of which there are two per boiler connected through pipes to an outside pressure tank. There has not been sufficient experience in starting up with river coal to train the operators thoroughly or to determine the best procedure and minimum amount of oil required, but experience to date has been as follows: When starting up after a weekday bank of approximately six hr. the torches were burned for 10 to 15 min. and consumed an average of about 20 gal. (75.7 l.) of oil per boiler. On individual days the consumption was as low as 10 gal. (37.8 l.). After a weekend bank of approximately 30 hr. the torches were used for 20 to 30 min. consuming about 80 gal. (303 l.) of oil. In starting up a cold boiler with straight river coal it is necessary to burn the torches for 35 to 45 min. A single measurement showed a consumption of about 125 gal. (473 l.).

One hundred per cent anthracite coal is not well adapted to high flow operation with many starts and stops and fluctuating loads. A scheme is under consideration to preheat the combustion air electrically during the high-flow period just before the morning peak, using otherwise wasted hydroelectric energy to shorten the starting period, to replace in part the large quantity of kerosene or fuel oil, and to save a considerable amount of now unburned fuel. Straight anthracite is also not suitable at Holtwood in very low flow when the steam plant is carrying the base load because of the reduced output of the mills. The latter objection could of course be overcome by installing more pulverizing capacity.

The river coal is abrasive and contains a varying amount of sand and small pebbles causing a large increase in the cost of maintenance of the preparation plant. Even small amounts of bituminous coal seem to act as a cushion or lubricant and reduce the wear on the mills.

The pulverizing mill balls are normally used until they have lost about 28.5 per cent of their initial weight, the latter being about 525 lb. (238 kg.) per ball. In milling straight anthracite, the average output is about 220 net tons per ball or 880 net tons for a set of balls. At rated capacity this would give an average life of about 195 hr. The material cost of balls is about 16.2 cents per net ton of coal ground.

The largest item in maintenance when using river coal is renewal of grinding rings. The life of a ring in tons is about 2060, and the cost of rings without labor is about 38 cents per net ton of coal. Operating and maintenance costs at the preparation plant, exclusive of power, during a five weeks run with anthracite, generating 3,284,000 kw-hr. under high-flow loading conditions, were as follows:

Operating labor	$.3435	per net ton
Supplies	.0175	" " "
Maintenance material	.8677	" " "
" labor	.0877	" " "
Total	$1.3164	" " "

During the above run the average ash content was 18.7 per cent dry basis, *i. e.*, 2.0 per cent higher than the average per cent for the year (16.7 per cent).

It is believed that due to a better understanding of the cause of yoke breakage, the cost of which amounted to 14 cents per net ton during the test period, this item could be greatly reduced.

A mixture of two kinds of coal is obtained by drawing bituminous and anthracite respectively from the two raw coal bunkers simultaneously upon the drag conveyor which discharges the coal into the dryer where it becomes thoroughly mixed. There has been no trouble due to separation of the two kinds of coal in the dryer, conveyor, mills, or transport system. A 50-50 mixture has been found entirely satisfactory for high flow fluctuating load operation.

The river coal dredging season lasts for only seven to nine months, depending on weather and river conditions. Fortunately this coal is particularly well adapted for storage purposes. The price of the raw coal is low, resulting in a minimum investment tied up in storage. The coal can be piled to any depth and does not deteriorate. In fact there is a certain improvement in that some of the moisture in the freshly delivered coal will drain off. For these reasons the fuel is particularly suited for use in a steam plant which is supplementary to a variable flow hydroelectric

development, as it is not possible to make accurate forecasts of the coal requirements.

Much study has been devoted to the combustion problem when using anthracite and to the proper construction and adjustment of the burners, air ports, primary and secondary air combinations, etc., but there is still need for further investigation along these lines. The Holtwood plant has proved that this low grade fuel can be burned successfully in pulverized form. The proportionate amount of anthracite actually used has so far been controlled more by practical considerations of supply then by conditions of operation and it is hoped that in the future a still greater amount can be used.

In actual practise it has been found that the guaranteed degree of fineness of pulverizing quoted above is not necessary. The present operating standard is 70 per cent for bituminous and for mixtures and 75 per cent for anthracite alone.

Results of tests on the dryer when treating river anthracite were as follows:

	Maximum Output of dryer	Average operation
Moisture entering dryer........	11.30 per cent	11.30 per cent
Moisture at dryer outlet.......	4.15 per cent	2.0 per cent
Moisture at mill inlet..........	2.41 per cent	1.0 per cent

Pulverized anthracite could not be burned successfully in the dryer and untreated river coal is now burned on hand-fired grates under the dryer. The coal fired per net ton of anthracite input to the dryer was 55.7 lb. (25.3 kg.). The heat units fired per pound of water evaporated in the dryer was 4100 B. t. u. (2277 kg-cal. per kg. of water).

Outage of Units. The excellent outage record of the Holtwood steam units shows that to a great extent the desire for maximum service reliability has been met. In about 21 months of operation of two units the total outage due to breakdowns or repairs of mechanical or electrical trouble has been 390 hr. or 1.26 per cent of the total unit hours in the period. This time could have been considerably reduced if necessary.

The only case of mechanical breakdown in the generating units and their auxiliaries was a shearing of two blades on the eighth stage wheel of one unit. In passing through the ninth or last stage these broken blades slightly damaged the ninth stage blading and then punctured four condenser tubes. As this trouble was not observed at the time it occurred, the unit was operated for several days until the damage to the tubes was discovered in the course of periodic tests on conductivity of condensate. It was then taken out at first for temporary repairs and a few weeks later for permanent replacement of the two damaged stages, but at the time the trouble was discovered the unit could have remained in service for a longer period if necessary.

The only major damage to the electrical equipment occurred during a severe local lightning storm, which caused a spillover between the high-tension and low-tension bushings on one of the 70-kv. step-up transformers, the low-tension side of which was connected to the same bus as the turbo-generator. The high voltage to which the generator in this way was exposed caused a puncture in the winding (2nd coil from the high voltage end out of 20), the flash taking place from winding to a projecting part of the supporting iron ring. The balanced relays tripped the oil circuit breaker and generator field immediately. The generator was energized 1½ minutes later and operated satisfactorily for six months, the puncture not being discovered until at the time of the annually scheduled routine inspection and disassembly of the unit. Only two armature coils had to be replaced requiring a total of 10 days of single shift work, the material being taken from stock. The fact that the unit could operate satisfactorily so long with a puncture in the armature winding is probably due to the fact that the system is operated with its neutral ungrounded.

The experience of other companies in respect to the capacity reducing effect of breakdowns may not have been as favorable with similar types of unit as the above described two accidents may indicate. But even if these two occurrences might have caused an immediate though temporary capacity outage at the Holtwood plant, the liberal provisions for spare equipment as practised for a number of years by the operating companies connected to the Holtwood system, would have permitted the bringing in of spare capacity, so that service should not have been affected by these breakdowns. Particularly on a system that does not depend wholly on steam power but draws a good portion of its requirements from a variable-flow hydroelectric plant equipped with pondage, such outages of a few hours or days can be readily taken care of during the low-flow period by the a-c. storage capacity, *i. e.*, the quick starting ability of the hydroelectric units referred to in the general description of the Holtwood system.

Minor Difficulties

As might be expected when building a plant in which so many different requirements have to be met deviating from usual practise, a great many minor difficulties have been experienced before satisfactory performance could be obtained from every piece of equipment. A few brief statements on these experiences may be of interest.

Drag Conveyer. The coupling between motor and conveyer broke several times on account of overload and jamming, caused by the type of slide gates employed at the outlets of the raw coal bunkers. When the slide gates opened wide the coal flooded and clogged the conveyer, and when only partly opened the wet river coal had a tendency to arch. After skirt plates were installed between bunker outlets and conveyer

and a shear pin was inserted in coupling, quite satisfactory operation was obtained.

Dryer. Attaching angles to the lifting blades of the drum greatly improved the performance of the dryer, although it has not yet fully met the guarantee, particularly in respect to river coal. The original plan of burning pulverized anthracite in the dryer had to be abandoned and hand-firing on pin hole grates, under forced draft, was finally adopted as the most satisfactory solution. The magnet in the discharge spout of the dryer did not remove all the tramp iron from the dried fuel before passing through the mills; this trouble was largely eliminated by placing three additional magnets along the spouts leading to the mills.

Explosions. So far only two explosions have been experienced, both of which can be traced back to excessive temperature in the dryer shell at high rating, aided by the presence of combustible foreign material. Damage was slight in one case but in the other the original explosion in the boot of the bucket elevator was followed by several smaller explosions, damaging the casing of the elevator. The vent stack at the top of the elevator casing was enlarged, steam lines were provided in the dryer, and an inspection window was cut in at the outlet end of the dryer. It is believed that these arrangements will greatly help to prevent explosions or to minimize their severity.

As a safe guard against explosions, dust is not allowed to accumulate in the mill house or in the dryer. The labor and expense of preventing such accumulations in the dryer have been reduced by installing soot blowers at points where dust might collect.

Mill Foundations. Regrouting of base rings and replacement of broken anchor bolts have been necessary at intervals, usually after a prolonged run of 100 per cent anthracite. The motor foundations as originally constructed developed serious cracks, but after they were enlarged no further trouble was experienced.

Mill House Lighting. Considerable difficulty was experienced at first with lighting in the mill house, due to breakage of filament from mill vibration. The lighting system was changed from 220 to 110 volts in order to take advantage of the greater mechanical strength of the lower-voltage filament. This only partially solved the problem. Special anti-vibration fixtures were then developed in conjunction with a fixture manufacturer. These now make possible normal lamp life.

Coal Transport Pumps. The pumps require a slightly larger amount of air than anticipated. They operate satisfactorily for either kind of fuel and for mixtures. The wear when pumping anthracite, though not excessive, is expected to be reduced by stelliting the periphery of the screw.

Fire in the Pulverized Coal Bunkers. On two occasions small smoldering fires started in the pulverized fuel bunkers. These were easily smothered by closing all vent openings and by slowly drawing down the stored fuel through the burners. These fires were probably started by some abnormal or temporary condition or quality of coal, as during a number of months two idle pulverized coal bins were normally kept full and coal has lain occasionally in a bin for several weeks without trouble.

Coal Feeders. Considerable wear was experienced on the coal feeders with anthracite. Hard metal studs were placed on the periphery of the screws, which compensated for the reduced diameter and maintained more equal coal feed to the burners.

Adjustment of Burners. In an effort to prevent secondary combustion within the boiler tubes, experiments were conducted with several devices for producing turbulency, a longer flame, and more thorough mixing of coal and air as discharged from the burners. One of these devices consisted of an aspirator discharging into the coal stream at the top of each burner. This caused the flames to impinge on the front wall and eroded them badly. The whirling type mixer now in use has proved fairly satisfactory for average ratings on both kinds of fuel. No experience has been obtained as yet over full range of rating.

Slagging of Bottom Tubes. In the early stages of operation with bituminous coal slagging of the two bottom rows of boiler tubes seriously interfered with ratings above 300 per cent. This difficulty was overcome by placing one soot blower at the front end between the two bottom rows of tubes, and a second one below the bottom tube at the rear entrance to the first pass, and by providing two additional lancing doors on each side of the boiler opposite the bottom tubes.

Dusting. Initially dusting was a problem of concern. The plates opposite the superheater and mud drum were replaced by an improved design. The dusting between side walls and end tube headers became serious due to the continuous motion between boiler casing and tubes, loosening the packing; this was largely overcome by installing holding plates of homemade design.

Secondary Air Dampers. This equipment does not function satisfactorily over the full range of rating for bituminous coal, anthracite, and various mixtures. Because of the wide variation in combustion conditions it is doubtful if these dampers can be made fully automatic.

Automatic Combustion Control. Control equipment of the furnace (coal feeders, stack dampers, induced draft fans) required considerable experimentation. Since the range of fan speed was extended automatic operation can now be relied upon over a range of loading sufficient for practical operation, but necessitating adjustment by hand for changes in the character of fuel.

Superheater. At the outset the superheat steam temperature was somewhat lower than specified; an exploration of the superheat space showed that a considerable part of the hot gases was short circuited around the end of the first pass baffle; the baffle was

extended to the tubes with some increase in temperature; by further extending the baffle all the way through the superheater tubes the gases were forced to pass thoroughly through the superheat tubes before entering the second pass and the desired superheat was obtained at the expense of a slight increase in draft loss.

Conclusion

The relatively wide range of operating conditions at the Holtwood steam plant in respect to character of fuel, amount of generation, shape of load curve, coordination with hydroelectric plant, etc., involved a number of interesting problems in design and operation for which only a limited amount of experience was available from other installations. It is felt that nearly all these major problems have been solved satisfactorily, but there is still need for further experimentation to secure the best possible results from the equipment now installed.

Auxiliary Power at Richmond Station

Auxiliary Power System and Tests on House Turbine Generator

BY J. W. ANDERSON[1] and A. C. MONTEITH[2]
Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—*This paper describes the auxiliary power system of the Richmond Generating Station of the Philadelphia Electric Company, mentioning briefly some of the factors which influenced the design of the system and discusses the starting of large motors at full voltage from an auxiliary turbine generator.*

* * * * *

It is the purpose of this paper to describe the auxiliary power system of the Richmond Generating Station of The Philadelphia Electric Company, mentioning briefly some of the factors which influenced the design of the system, and to discuss particularly a most important feature of this system; namely, the starting of large motors at full voltage from an auxiliary turbine generator. At the time this system was designed practically no data were available on this subject, and as there seems to be a general trend in power station design toward the use of auxiliary turbine generators or auxiliary generators direct-connected to main units, it is believed that a discussion of some of the factors involved and the results of tests made at Richmond Station after installation will be of value.

I. Description of Auxiliary Power System

General. Richmond Station is located in the northeastern section of Philadelphia along the Delaware River, about five miles from the central part of the city.

At the present time, the capacity of the station is 120,000 kw., made up of two turbine generators, each rated 60,000 kw., 0.85 power factor, 13,800-14,400 volts, three-phase, 60 cycles, 1800 rev. per min. Ultimately the plant will have a rating of at least 720,000 kw., and will consist of three separate building sections, each housing four turbo generators of at least 60,000 kw. capacity.

The first building section, which was completely constructed in the initial development, comprises three main parts; namely, boiler room, turbine hall, and switch house, with the boiler room nearest the river. Ultimately the boiler room will house 24 boilers. Twelve boilers have been installed initially, each rated at 1570 hp. and equipped with a superheater, an economizer, and an air preheater. Two induced-draft and one forced-draft fans are provided per boiler. Included in the turbine hall and its mezzanine galleries and basement are the main generating units (Fig. 1), condensers with their auxiliaries, heaters, evaporators, deaerators, boiler feed pumps, river and city water pumps, air compressors, auxiliary power generator and buses, generator and exciter field rheostats, main generator ventilating equipment, etc. In the switch house are installed duplicate 13,200-volt buses, oil circuit breakers, disconnecting switches, reactors, etc., all arranged for vertical phase isolation. A connecting building between the turbine hall and the switch house contains the d-c. power room, battery room, pipe room, and operating room. Transformers supplying all 2300-volt auxiliary power load and induction regulators for the three tie lines to Delaware Station are located outdoors between the turbine hall and the switch house.

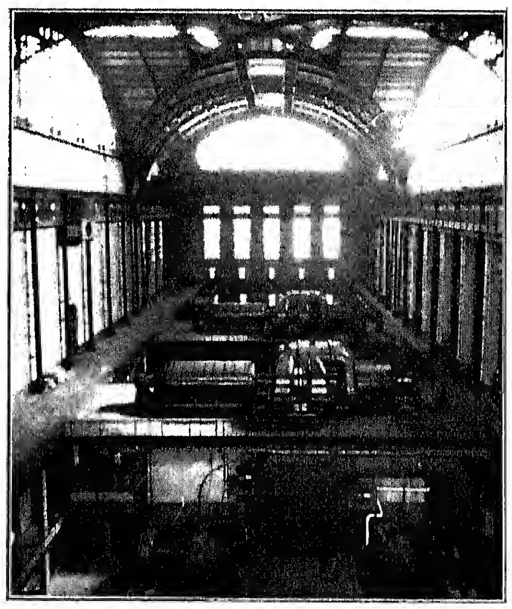

Fig. 1—Main Generating Units

Auxiliary Power Supply. The auxiliary power system at Richmond Station is radically different from the systems at Delaware and Chester Stations, other major plants of the Philadelphia Electric system, due principally to differences in methods used for maintaining heat balance.

At Delaware and Chester, although electric drive is used extensively for auxiliaries, a number of the auxiliaries have steam drive; all boiler feed pumps are steam driven; one of the duplicate circulating water pumps provided for each unit has a dual drive by turbine and motor, the other circulating water pump

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

being motor-driven and used only in emergencies; one of the two air pumps and one of the two condensate pumps of each unit are steam driven, the other air and condensate pumps being motor driven. Exhaust steam for feed water heating is obtained by running the proper number of steam-driven air and condensate pumps with the boiler feed pumps and dual drive circulating water pumps. Small adjustments to maintain the proper amount of exhaust steam are made automatically by varying the governor setting on the turbine of dual drive circulating water pumps. In view of the fact that steam drive is provided for those auxiliaries which are most essential to the continuous operation of these plants, a supply from the main buses of the station is entirely satisfactory for service to the electrically driven auxiliaries; consequently a layout wherein the entire alternating current auxiliary power supply is obtained from transformers connected to the main 13,200-volt buses was adopted for Delaware and Chester stations.

For Richmond station, investigations made subsequent to a study of many of the most modern plants in this country and abroad, indicated that for the conditions under which Richmond would operate, three-stage heating would be most economical. Accordingly, bleeding of the main turbines was adopted. Bleeder connections are provided at the tenth, twelfth, fifteenth, and eighteenth stages (the turbines are 20-stage, Curtis type). Tenth stage bleeder steam is used only to heat the building and to increase the capacity of evaporators in case of any excessive demands for make-up water. The three other stages are used in the normal operation of the heater system.

The adoption of stage bleeding for Richmond not only eliminated any need for steam driven auxiliaries as regularly operating units, but made such drive undesirable from the standpoint of operating economy. Electric drive was therefore a necessity for all auxiliaries except those installed for standby service only.

The requirement of electrically-driven auxiliaries carried with it the further requirement of a source of electrical power having the highest degree of reliability for service to motors driving the most essential auxiliaries, such as boiler feed pumps, circulating water pumps, air and condensate pumps, generator ventilating fans, etc. Consequently, a supply from the main buses of the station could not be used for these auxiliaries, since in case of bus trouble or severe system disturbances, this source might be so seriously affected as to cause the loss of these most important auxiliaries. However, a supply from the main buses was adopted for the less essential auxiliaries and for those auxiliaries, such as boiler fans, which it might be desirable to have shut down in case of a sudden loss of station load.

Three alternatives were considered in deciding on a source of power for the essential auxiliaries; namely, auxiliary turbine generators, auxiliary generators on main unit shafts, and transformers connected to main generator leads between the generator terminals and the main oil circuit breaker. Both first cost and operating cost of turbine generators eliminated them from consideration as regularly operating units, although an emergency non-condensing unit, suitable for starting large motors at full voltage as discussed elsewhere in this paper, is provided. Generators on the main unit shaft, although providing auxiliary power at low cost, added undesirable mechanical complications to the main unit, and as it was desired to have shaft-end exciters on the Richmond units because of their successful operation at other plants, this alternative was also eliminated from consideration. Accordingly, the use of transformers connected to main generator leads was adopted. This scheme has the advantages of high reliability, low first cost, and low operating cost, and although it introduces an electrical complication, the great reliability of modern transformers made this complication of but slight importance. The scheme is also open to the objection that should the unit be disconnected automatically while carrying a heavy load, either the overspeed device on the main turbine may operate causing the loss of auxiliaries, or, if the overspeed device does not operate, the auxiliary system will be subjected to a high overvoltage until the voltage regulator functions to bring the voltage back to normal. This objection can be overcome by careful adjustment of the overspeed device and by installing equipment designed to withstand the overvoltage. Equipment so designed has the advantage of high factor of safety under normal operating conditions.

As installed, the auxiliary power system at Richmond Station consists of five principal parts as follows:

1. A 2300-volt, three-phase, 60-cycle supply for boiler fan motors and large less essential auxiliaries.
2. A 2300-volt, three-phase, 60-cycle supply for essential auxiliaries.
3. A 230/115-volt, two-phase, 60-cycle supply for small auxiliaries, lighting, etc.
4. A 250-volt, direct-current supply for stoker motors, emergency excitation, etc.
5. A 250-volt, direct-current supply for control of oil circuit breakers, etc.

The 2300-volt supply for boiler fan motors and large less essential auxiliaries such as motor generator sets, fire and water pumps, is obtained from three (ultimately four) 3750-kv-a. oil-immersed, self-cooled transformer banks located between the switchhouse and turbine hall and supplied from the main 13,200-volt buses in the same manner as outgoing lines. These banks feed duplicate sectionalized 2300-volt buses located between turbine hall and the boiler room so that cable runs are of minimum length.

The 2300-volt supply for essential auxiliaries is laid out on the unit principle. A 2500-kv-a., oil-immersed, self-cooled transformer bank, also located outdoors between the switchhouse and turbine hall, is connected directly to the terminals of each generator and supplies a short bus installed on a gallery under the turbine hall

floor. All essential auxiliaries associated with the generating unit are connected to this bus. To supply these auxiliaries while starting the unit, and also to act as reserve sources, each of these unit auxiliary buses is provided with two ties, one to the general 2300-volt system and one to another 2300-volt bus to which the auxiliary turbine generator may be connected. Thus each unit auxiliary bus has three separate sources of power. The breakers controlling these sources are interlocked so that normally no two of them can be paralleled, although provision is made to alter the interlocking by a synchronizing plug in case it is desired to parallel the auxiliary generator with the general 2300-volt system. In starting up a generator, the unit bus is usually supplied from the general 2300 volt system, and after the machine has been synchronized and connected to the station bus, the unit bus is connected to the transformer bank on the generator terminals. Suitable relays give an audible alarm in event of failure of voltage on the unit bus.

The 230/115-volt, two-phase supply is obtained from two (ultimately three) 1000-kv-a., oil-immersed, self-cooled, Scott-connected transformer banks supplied from the general 2300-volt system and located outdoors under the 230-volt power room at one end of the turbine hall. Adjacent to the 230-volt power room is an emergency valve control room from which all main electrically-operated valves can be closed.

The 250-volt direct-current system provided for the supply of stoker motors, emergency excitation, emergency lighting (automatic on failure of the alternating current supply), miscellaneous power, etc., is fed by three 200-kw. motor-generator sets and a 156 cell storage battery. The other 250-volt direct-current system supplies power for operating oil circuit breakers, valve motors, indicating lamps, etc., and is fed by two 20-kw. motor-generator sets and two 120 cell storage batteries. This system is entirely separate from the stoker and emergency excitation system, although an emergency tie is provided between the two. Control circuits of main and selector oil circuit breakers are operated on separate parts of the control system.

A diagram of the auxiliary power system at Richmond is shown in Fig. 2, which also indicates a typical normal method of operation. It will be noted that the system is so sectionalized that failure of any transformer bank, bus section, etc., will result in interruption to a minimum number of auxiliaries, and that such auxiliaries as may be affected can be either switched quickly to another source or replaced by duplicate units.

A list of the steam driven auxiliaries is also included in Fig. 2. All of these auxiliaries are intended for stand-by service only.

Motors. Table I lists the major auxiliary motors at Richmond, with their rating, type, method of starting, method of speed control, etc.

In general, all alternating-current motors above approximately 50 hp. are supplied at 2200 volts, three-phase, while those below are operated from the 220-volt, two-phase system. However, for special

TABLE I
MAJOR AUXILIARY MOTORS
RICHMOND STATION

Auxiliary	Motor rating	Type of motor	Starting	Speed control	Automatic restarting
Boiler feed pumps	550 hp.	Wound-rotor	Secondary resistance Push button	10 per cent range 18 points automatic	Yes
Circulating pumps	500 hp.	Squirrel-cage	Full voltage—Push button	....	Yes
Air pumps	50 hp.	Squirrel-cage	Full voltage—Push button	....	Yes
Condensate pumps	100 hp.	Squirrel-cage	Full voltage—Push button	....	Yes
Generator ventilating fans	150 hp.	Squirrel-cage	Full voltage—Push button	....	Yes
Forced draft fans	125 hp.	Wound-rotor	Secondary resistance Controller	50 per cent range 5 points	Yes
Induced draft fans	60 hp.	Wound-rotor	Secondary resistance Controller	50 per cent range 5 points	Yes
Stokers	15 hp.	D-c. shunt	Resistance—Controller	80 per cent range 22 points	No
Fire pump	200 hp.	Squirrel-cage	Compensator	....	No
River water pumps	275 hp.	Squirrel-cage	Full voltage automatic from float switch	....	Yes
Air compressors	190 hp.	Synchronous	Full voltage—Push button	....	No
Stoker supply motor generator sets	290 hp.	Synchronous	Full voltage—Push button	....	No

services such as those required for cranes or in the screen house, motors as large as 80 hp. are supplied at 220 volts.

In the design of the auxiliary power system, careful investigations were made as to the proper types of motors to be installed for the various auxiliaries. In the case of boiler fans, several types were considered including brush shifting a-c. motors, d-c. motors with variable field and armature control, as well as the standard wound-rotor motor which was finally adopted. For stoker service, both a-c. and d-c. motors of various types were considered before a decision was reached to install the variable-speed d-c. shunt motor.

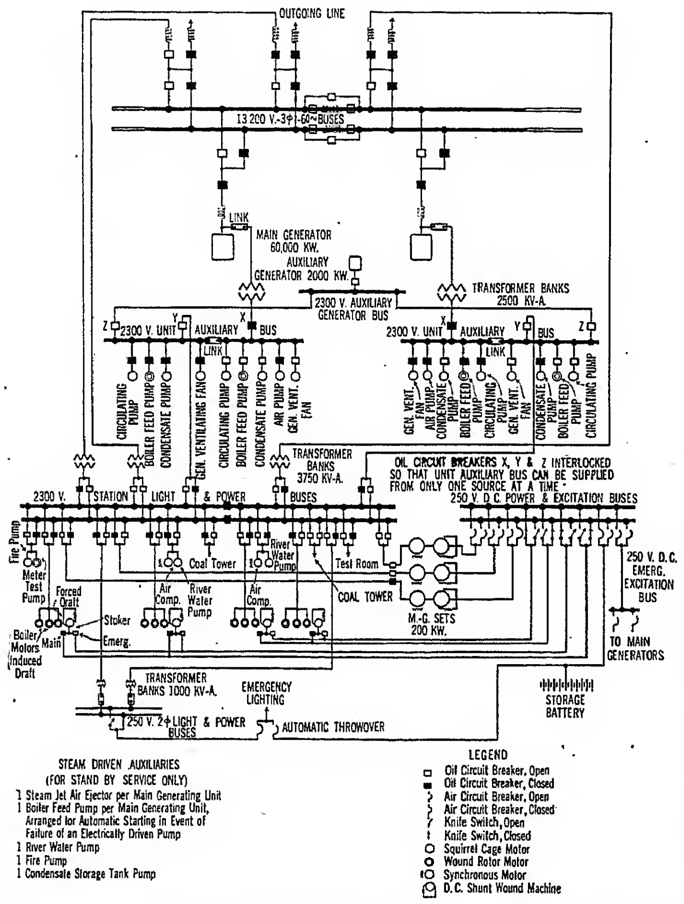

FIG. 2—STATION AUXILIARY SYSTEMS AND TYPICAL NORMAL METHOD OF OPERATION

Motor Controls. Boiler feed pump motors are started and stopped from push button stations near them. In starting, a block of resistance is inserted in the rotor circuit and is short-circuited automatically when the motor is up to speed. Speed control may be obtained either manually from a push button station or automatically from a pressure regulator set to maintain the proper differential between feed water and steam pressures. A pilot motor controlled by the push button station or by the pressure regulator operates a drum controller which varies the amount of resistance in the rotor circuit of the motor. In case of loss of voltage, the starting resistance is automatically connected in the circuit, and upon restoration of voltage, the motor again comes up to the proper operating point.

Wound-rotor motors driving draft fans are controlled from manually operated controllers located at the boiler control panels. Control equipment is so arranged that the controller may be set at the desired operating point, and the motors will come up to this speed without additional manipulation of the controller. In event of loss of voltage, contactors operate to connect all resistance in the rotor circuit, and when voltage is restored, the motor comes back to the operating point for which the controller is set.

In connection with the control of constant speed motors, careful consideration was given to the various methods of starting that were applicable; namely, compensator starting, reactor starting, and starting at full voltage.

When the older stations were placed in service compensator starting was used extensively. However, as is well known, this type of starting has several serious objections, when used in large power stations, the outstanding one of which is the danger to life that may result from failure of the compensator. Other less important objections are the fact that the motor is subjected to two heavy current inrushes, one at the time of starting and one at the time of throw-over from partial to full voltage, and the fact that automatic control with compensators is relatively complicated. As a result, reactors with shunt oil circuit breakers rather than compensators were used in several new installations, and on a number of existing installations compensator starting was replaced by reactor starting. However, although reactor starting greatly lessens danger to life, results in only one shock of current inrush to the motor, and is easily adapted to automatic control, it has the disadvantages of relatively high cost and large space requirements. In considering the type of starting to be used at Richmond Station, all of these features of compensator and reactor starting were taken into account and compared with starting at full voltage, with the result that full-voltage starting was adopted for all of the most important constant-speed auxiliaries except the fire pump, which had to be installed for construction purposes prior to the final design of the auxiliary system. Full-voltage starting not only eliminates the explosion hazard, but results in installations of minimum cost and control systems of the utmost simplicity wherein automatic restarting after an interruption is easily obtained. This last feature is particularly important, since the station operators can concentrate their attention elsewhere at times of trouble. This type of starting has, of course, the disadvantages of high current inrush during starting, possible damage to the motor because of the heavy mechanical forces to which the windings are subjected, and possible damage to the driven equipment because of the high starting torque developed. However, with the usual large amount of generating capacity in

operation, the voltage dip resulting from the current inrush is negligible, and by proper mechanical design, the possibility of damage to the motor or to the driven equipment is very remote.

As installed, the synchronous motors at Richmond are controlled from push button stations. Pressing the starting button closes an oil-immersed contactor which connects the motor to the line. The field contactor closes automatically at the proper time. Protective equipment includes relays which open the field circuit

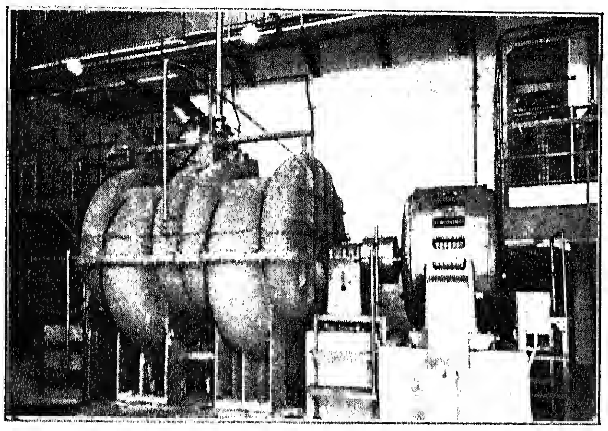

FIG. 3—CIRCULATING PUMP AND MOTOR

in event of loss of a-c. voltage and which disconnect the motor from the line in case of loss of field, and also a time-delay low-voltage relay which on failure of a-c. voltage opens the oil-immersed contactor but which in case of short circuit in the armature winding, permits the clearing of the line oil circuit breaker before the contactor opens.

Control equipment for squirrel-cage motors consists merely of an oil circuit breaker in the motor leads controlled from a twin pull button switch of the usual type located near the motor.

As shown in Table I, the largest constant speed motors started at full voltage are those driving circulating water pumps. These motors (Fig. 3) are rated at 500 hp., 2200 volts, three-phase, 60 cycles, 225 rev. per min. Full-load current is approximately 140 amperes, and starting current is around five times this value. Although these motors can be easily started under normal conditions, when they are supplied either from the main station busses or directly from the main generating units, the question of starting them from the auxiliary turbine generator was a problem of paramount importance, and was given very careful study both by the engineers of the Philadelphia Electric Company and by those of the Westinghouse Electric and Manufacturing Company, which furnished the auxiliary turbine generator.

As the auxiliary unit was for stand-by service only, it was desired, of course, to provide as small a unit as possible in order to keep investment costs at a minimum. However, in case of a complete interruption to the station, the unit must be able to start and carry sufficient auxiliaries to permit resumption of service. Since the circulating water pumps were the largest auxiliaries to be considered, the ability to start three such pumps in succession with valves closed was fixed as the duty to be met by the auxiliary unit. As a result of the study of this question, a unit of special design with a standard vibrating type voltage regulator was installed. The unit is rated 2000 kw., 3333 kv-a., 0.6 power factor, 2300 volts, three-phase, 60 cycles, 3600 rev. per min. (Fig. 4) and can be brought up to speed ready for load in fifteen seconds. Starting is accomplished by operating a motor-driven bearing oil pump; when the bearing oil has reached the proper pressure, a contact-making pressure gage opens an electrically-operated valve in the steam line to the turbine.

II. FULL VOLTAGE STARTING OF LARGE MOTORS

General. On account of the greater simplicity and reliability of the control equipment, and the ease with which automatic restarting can be obtained, the decided tendency has been towards the use of full-voltage starting on as many of the auxiliary motors as possible. A careful study of the problem of properly insulating motors for this class of service has been made, and the results of this study have been presented to the Institute.[3] As a result of these and subsequent tests, there seems to be no question that all squirrel-cage induction motor windings can be braced to withstand the mechanical effect due to full-voltage starting. A

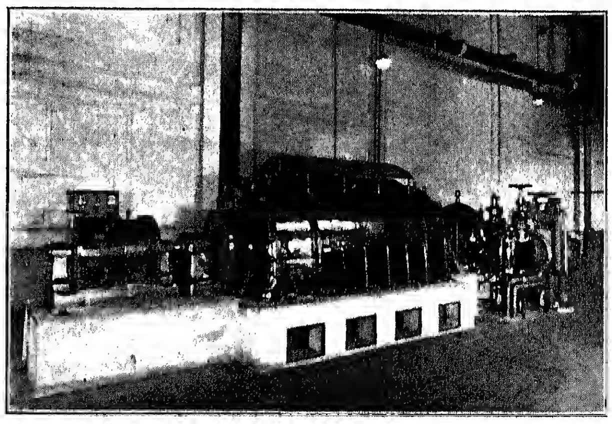

FIG. 4—AUXILIARY TURBINE GENERATOR

large number of the motors designed for low-voltage starting can be used when full-voltage starting is desired. The large high-speed motors, which have comparatively high starting currents and long coil extensions, require some additional bracing.

In power stations, where the motors are started on the main auxiliary bus fed from the main unit, the

3. J. L. Rylander, *Effect of Full Voltage Starting on the Windings of Squirrel-Cage Induction Motors*, A. I. E. E. TRANS., Vol. 44, 1925, p. 53.

starting of the motors on full voltage is usually a matter of mechanical considerations of the load. The drop in voltage at the motor terminals is due to the leakage reactive drop of the transformers and the drop in the cable and bus connecting the motor to the transformers. This is small as the transformer capacity is much greater than the largest motor to be started.

When the auxiliaries are started from a small auxiliary unit not only the voltage drop due to the reactance of the generator and the drop in the leads, but also the effect of armature reaction must be considered. This may appear serious, when it is desired to start large motors, but there are several inherent properties in this particular application which make it possible to start such motors, provided good voltage regulation is not essential during the starting period.

Effect of Generator Characteristics. If calculations of the voltage drop are made assuming that both the generator reactance and armature reaction become effective instantly, and that the impedance of the load remains constant, a low value of voltage is arrived at. These are probably questionable assumptions but they are commonly used in making calculations. Since it takes time for the armature reaction to become fully effective, and also the effective motor impedance increases with speed, smaller voltage drops are actually obtained on test. When a three-phase short circuit is placed on a generator of this type, the flux will have reached a constant value in about 1.5 seconds. This is an average value for several machines. Increasing the external reactance considerably increases the time for the flux to become constant.

Low internal reactance is desirable as it reduces the instantaneous drop in voltage when a load is applied to the generator. Low reactance is inherent in the comparatively low-capacity high-speed turbine generators used for auxiliary units.

When hand regulation is used, high short-circuit ratio or good inherent voltage regulation is desirable, as the starting currents of squirrel-cage induction motors are of low power factor. This can be obtained either by using a generator of special design or a larger generator than necessary for the load or a combination of the two.

Voltage Regulation. A voltage regulator is essential when severe duty is placed on the auxiliary unit. It will not only keep the voltage constant on the auxiliary bus during normal operation but will maintain better voltage conditions when a motor is being started. High short-circuit ratio is not as essential when a voltage regulator is used. With the voltage regulator in operation the speed of response of the exciter has a decided bearing on the voltage drop obtained when a large motor is started. The higher the speed of response the nearer the effect of armature reaction is eliminated. A high speed of response is inherent in small high-speed exciters.

Effect of Load Characteristics. The characteristics of the load have a decided bearing on the size of motors that can be started with a given voltage drop. The motors driven from the auxiliary generator are usually the condensate, circulating water and boiler feed water pumps. All of these have torque characteristics which vary with speed. The torque on the circulating water pump motor varies approximately as the square of the speed. The others are nearly up to speed before the pump takes on load. The condensate pump motor is comparatively small, while the boiler feed pump is usually driven by a wound-rotor motor. The circulating water pump motor is in most cases the largest to be considered. At zero speed, the torque is only that necessary to overcome the static friction of the bearings. This allows considerable torque for acceleration, so that the motor will come up to speed very quickly and the low power factor starting current will decrease to normal full-load current of comparatively high power factor before the armature reaction has become fully effective. The voltage drop will, therefore, be less than if it took longer for the motor to reach full speed.

From the above it is seen that, if all factors are considered, it is difficult to calculate the voltage drop with any degree of accuracy. When Richmond station was being designed, calculations, using a step-by-step method, were made for several combinations of starting the circulating water pump motors. When the equipment was installed, tests which were made to determine the voltage drop, indicated better voltage conditions than calculated because pessimistic assumptions were used.

Tests at Richmond Station. The following is a brief description of the generator and the circulating water pump motors installed in the Richmond Station and the tests run.

The auxiliary generator is rated at 3333 kv-a., 0.6 power factor, three-phase, 60-cycle, 2300 volts at 3600 rev. per min. The leakage reactance is 5.6 per cent and the short-circuit ratio is about 1.7. No-load field current for 2300 volts is 68 amperes. The direct-connected self-excited exciter is rated at 33 kw., 250 volts and is a four-pole unit.

The 32-pole motors driving the circulating water pumps are rated at 500 hp., three-phase, 60 cycles and 2200 volts. These motors have a starting torque equal to full-load torque, and a pull-out torque of 2.8 times full-load torque. The slip at full load is 3.3 per cent of synchronous speed. The pump has a calculated torque characteristic which varies approximately as the square of the speed down to 70 rev. per min. Below 50 rev. per min. the torque increases with decrease of speed. The calculated torque with the valve closed is 65 per cent of full-load torque at full speed.

Since the auxiliary generator was required to start three circulating pumps in succession and only two were available for the test, an equivalent load, consisting of two generator ventilating fans driven by 150-hp., squirrel-cage motors and two boiler draft fans driven by 125-hp. wound-rotor motors, was used. The two

pumps used were duplicate units on one condenser. In making the tests the generator and the above mentioned motors were isolated from the remainder of the station, so that complete tests could be made without affecting the operation of the station. Two six-element oscillographs with eight-foot films were used in obtaining records of the tests. Besides taking records of the auxiliary generator and exciter voltages

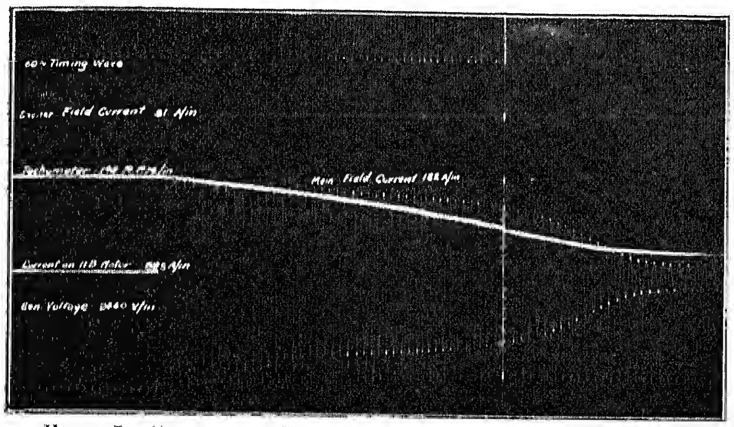

Fig. 5—Starting One Motor with Fixed Generator Excitation

and currents, one oscillograph element was connected to a special magneto, giving an indication of the speed of one pump at all times. The tests fall in four distinct groups.

Group I. One circulating water pump motor was started with no-load excitation on the auxiliary generator. With the pump valve in the open and closed position tests were made with the generator under control of the vibrating type of regulator and also with fixed excitation.

Group II. With the equivalent of one motor running and with the voltage adjusted to normal, a second motor was started with the generator under the control of the automatic voltage regulator and also with fixed excitation The pump valves were open for these and subsequent tests.

Group III. With the equivalent of two motors running, and with the voltage adjusted to normal, a third motor was started with the generator under the control of the automatic voltage regulator and also with fixed excitation.

Group IV. With no-load excitation on the generator, the two ventilating fans, the two boiler draft fans, and one circulating pump motor were started together, and, after an interval, a second circulating pump motor was started. These tests were made with the generator under control of the automatic voltage regulator and with fixed excitation.

Several other miscellaneous tests which were made will be referred to when the results of the above tests are reviewed.

Tests Results. Sections of two of the oscillograms taken are shown. Fig. 5 shows the starting of a motor with fixed excitation on the generator. Fig.6 shows the starting of a motor with the generator under control of the automatic voltage regulator. Oscillograms taken simultaneously with those shown give the generator currents, exciter terminal voltage, and a timing wave. For the oscillograms shown the generator and motor currents were the same. In order to make the test results easier to interpret, the various values have been scaled off the oscillograms and plotted. The curves with broken lines indicate the results when the automatic voltage regulator was in operation, while those with solid lines indicate the results of the tests when fixed excitation was used on the generator. This same notation will be used throughout.

The results of the tests under Group I are shown in Fig. 7. With fixed excitation, the voltage dropped from 2350 volts to 1850 volts in about one second and the motor accelerated to 67 per cent of synchronous speed. From this point up to full-load speed the impedance of the motor increased rapidly, so that the current decreased. Assuming that the motor impedance is constant and that the effect of reactance and armature reaction becomes effective instantly, a value of 1400 volts is obtained with no-load excitation on the generator.

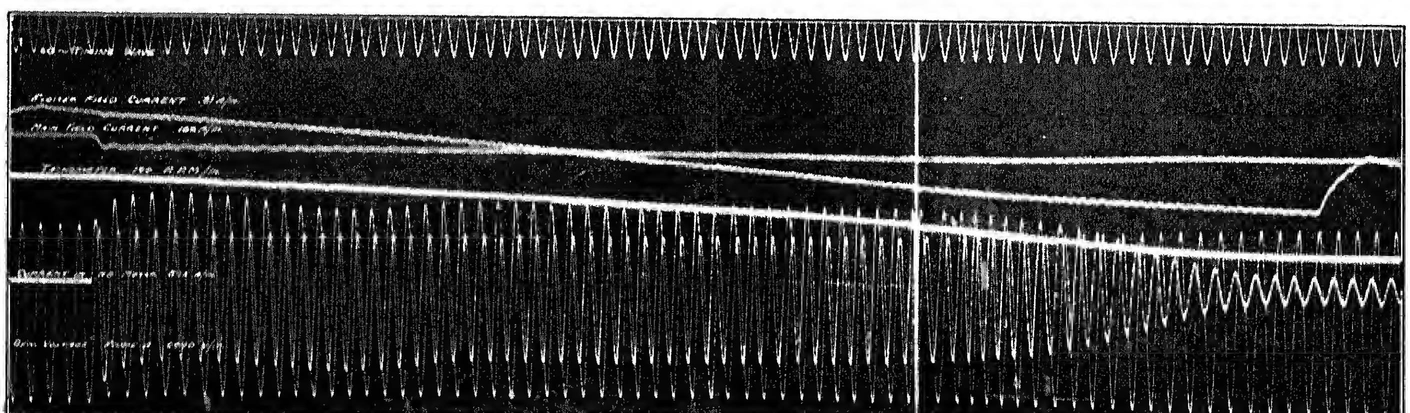

Fig. 6—Starting One Motor with Voltage Regulator in Operation

Whether the pump valves are open or closed makes very little difference on the time to accelerate the motor to full speed. For either condition the current decreased to approximately 110 amperes, gradually increasing to 140 amperes when the valve was open. The motor came up to full speed in both cases in 1.8 seconds with fixed excitation on the generator.

With the regulator in operation, a minimum of 2060 volts was reached in 0.4 seconds. The regulator became effective very quickly, bringing the voltage back to normal in 1.1 seconds. In this case it took 1.4

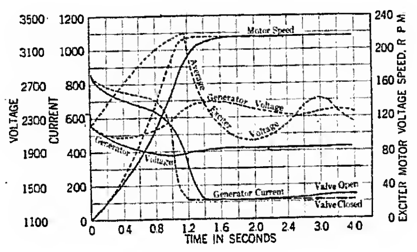

FIG. 7

seconds for the motor to come up to speed. The voltage was, therefore, normal before the motor reached full speed. The exciter terminal voltage built up from 110 to 220 volts in 1.1 seconds.

The results of the tests under Group II are shown in Fig. 8. Without the voltage regulator in operation, the voltage dropped to 1920 volts in one second, and the motor reached full speed in 1.6 seconds. With the regulator in operation, the voltage dropped to 2080 volts in 0.4 seconds, and the motor was up to full speed in 1.4 seconds.

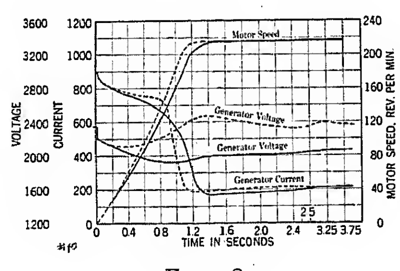

FIG. 8

The results of the tests under Group III are shown in Fig. 9. Without the voltage regulator in operation, the voltage was adjusted to 2540 volts on the generator with one motor running. The voltage dropped from 2540 to 2140 volts when the second motor was started, recovered to 2350 volts, and finally reached a minimum of 1600 volts when the third motor was started.

A record of the speed of the second motor was taken when the third motor was started. Although the voltage dropped considerably, the speed dropped gradually from 216 to 204 rev. per min. This drop in speed counteracted the voltage drop, so that the current taken by the motor only increased from 140 to 160 amperes. The inertia of the load already on the generator undoubtedly helped the conditions when the third motor was started. The tests show that the current taken by a motor actually decreases for a time. The effect of the inertia may be judged from two tests run. With the valve open and the condenser full of water, a test was made to see how long it would take the motor to stop. In four seconds the motor reversed, and at the end of nine seconds the motor had reached a maximum speed of 160 rev. per min. in this

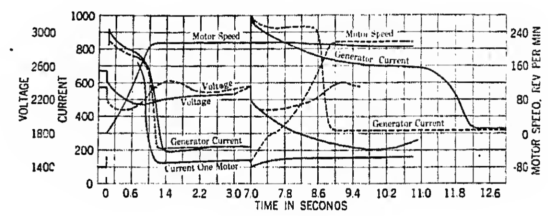

FIG. 9

direction, due to the water flowing out of the condenser. With the valve closed, it took about 40 seconds for the pump to stop.

With the voltage regulator in operation, the voltage dropped to 2080 when the second motor was started. The voltage had been restored to 2350 volts at the time of starting the third motor and dropped to 2070 in 0.4 seconds but was restored to normal in 1.7 seconds. In this case it took longer to bring the motor up to speed because it was running at 75 rev. per min. in a reverse direction when the voltage was applied. It took 0.6 second to stop the motor and a total of two seconds for the motor to reach full speed.

The results of the tests under Group IV are shown in Fig. 10. Without the voltage regulator in operation

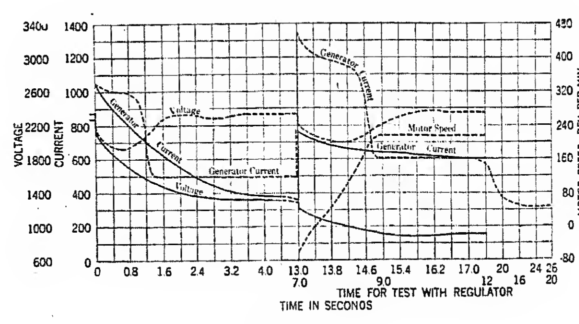

FIG. 10

the voltage dropped to 1300 volts in 13 seconds, and when the last circulating pump motor was started, the voltage dropped to 900 volts and remained there. The second pump was rotating in a reverse direction and the voltage was not high enough to produce sufficient torque to stop the pump before the test was discontinued.

Under regulator control the application of the first load caused the voltage to drop to 1920 volts in 0.6 second and it was restored to 2330 volts in two seconds.

When the second load was applied, the voltage dropped to 2000 volts in about one second and was restored to normal in 2.8 seconds. Again the pump was running at 70 rev. per min. in a reverse direction and it took a total of two seconds to start the motor.

The current, when the second load was applied, decreased rapidly to 600 amperes and remained at that value for a time, again falling to 315 amperes. The second drop no doubt indicates where some of the high inertia fans, started with the first load, approached full speed.

In no case did the average speed of the turbine fall more than 3 per cent. Although the currents were comparatively large the actual load was not excessive and came on gradually.

A test was made to determine the torque necessary to start the motor revolving. This was done by lowering the generator voltage and connecting the motor to the generator by closing the oil circuit breaker. It was found that with 750 volts on the generator, the motor revolved slowly. Considering that the starting torque varies as the square of the applied voltage, this indicates that it took approximately 11 per cent of full-load torque to start the motor revolving. This test was made after the motor had been run for a time.

It is seen from these tests that the actual voltage conditions are much better than calculated, such calculations being based on steady state conditions, assuming an instantaneous decrease of generator flux and constant motor impedance. The tests also show conclusively that an automatic voltage regulator has a decided stabilizing effect.

Recent Investigation of Transmission Line Operation

BY J. G. HEMSTREET[1]

Associate, A. I. E. E.

Synopsis.—*This paper discusses transmission line operating experience on the 140,000-volt isolated neutral system of the Consumers Power Company, Michigan.*

Careful inspections and tests have been made to determine the conditions existing relative to insulator flashover and the findings and results are shown by tables and curves.

Ground resistance or soil conditions appear to have a very decided effect on the number of flashovers on the various lines. The necessity of providing suitable arc protection to the line conductors is shown, as is also the soundness of certain theories and recommendations for increasing the reliability of transmission lines, based upon laboratory experiments.

Introduction

The design of an insulation system for high-voltage transmission lines that will be immune from failure during lightning storms or other abnormal conditions, is one of the most important problems confronting the transmission engineer at the present time. This is becoming increasingly so with the interconnection of large systems and the more exacting requirements of the consumers.

The experience of those who have been operating some of the larger systems should be of assistance in designing, in so far as possible, to guard against the difficulties that have been encountered, and it is with this thought in mind that the data in this paper are presented, as well as to add to the information on operating experience already available; also as a further check on certain theories and designs that have been and are proposed for the greater reliability of high-voltage transmission lines. This paper relates some experiences and the results of investigation of transmission line operation with particular reference to insulator flashover on the 140,000-volt system of the Consumers Power Company in Michigan. A map of this system is shown in Fig. 1.

1. Supt. of Operation, Consumers Power Co., Jackson, Mich.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

History

The matter of insulator flashover became of some concern a few years ago as the system increased in size. The flashovers in some cases caused voltage disturbances or circuit breaker operation and in a few instances failure of the line due to burning of the conductor or hardware at the lower end of the insulator string. The earlier lines were not equipped with any form of arc protection but in 1920, standard 15-in. arcing horns, (shown in Fig. 2), were installed on the Argenta-Battle Creek section which at that time was added to the system. Later in the year, the Jackson-Battle Creek section was added and was also equipped with the standard arcing horn. The Edenville-Saginaw-Flint sections were added in 1924. At the time these last two sections were being designed, there was considerable discussion as to the nature of the transients, set up in high-voltage systems, that caused flashover, and based upon the theory that the trouble was due to rather sustained high frequency

conditions[2], started by the original lightning discharge or some other cause, the insulator flux control was offered as a means of raising the flashover voltage of the insulator, as well as providing a horn as protection to

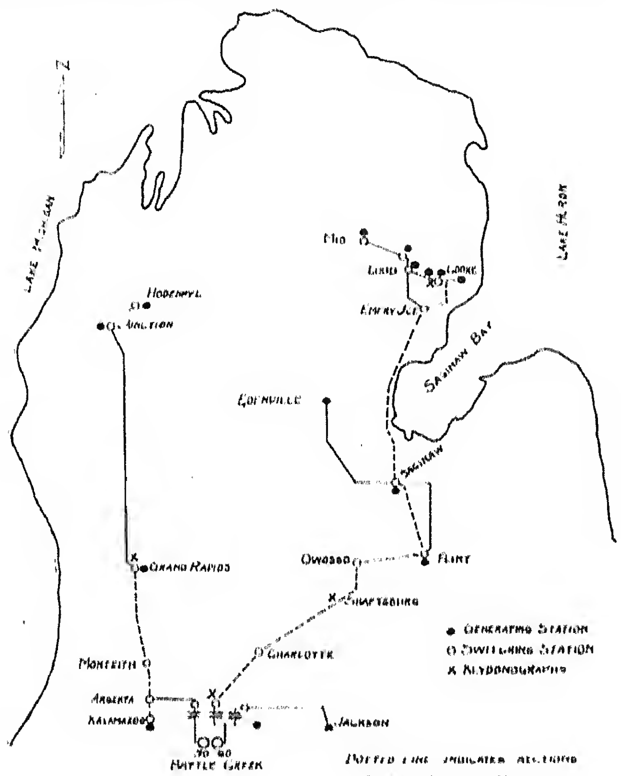

Fig. 1—Map of 140,000-Volt System

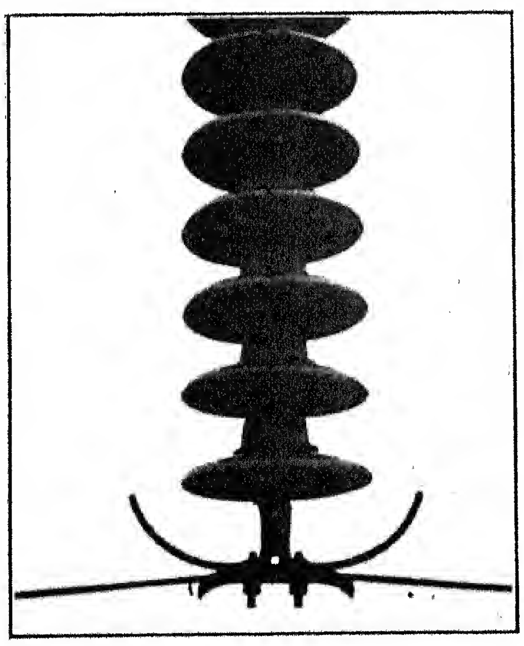

Fig. 2—Type of Arcing Horn Used

the conductor. The Consumers Power system being delta-connected throughout, the possibility of the existence of severe high-frequency disturbances was thought to be more likely at the time than would be the case on other systems operating with the neutral grounded, and this was thought possibly to be the cause of some of the trouble. These last two sections of line were equipped with the flux control, as shown in Fig. 3. All of the arcing horns and flux controls were installed on the lower end of the insulator strings only.

The development of the klydonograph[3] offered a means of determining the nature of the transients and four of these instruments were in service during 1925.

At the close of the 1925 lightning season, it was decided to make a careful inspection of the two sections of the transmission line added to the system during 1924. There had been no failures directly traceable to these sections but it was thought desirable to determine the exact conditions. The inspection was carried on with considerable care, an especially trained crew of men climbing each tower and carefully inspecting the insulators, conductors, and all parts of the tower tops, to locate any burns or evidence of insulator flashovers. Later, the inspection was extended to other parts of the system to obtain the comparative data, and also to locate and eliminate any weaknesses due to damaged conductors or other equipment. In only a very few cases could the damage be detected from the ground, nor had it been found by the regular patrol service.

Description of System

The system as shown on the map, Fig. 1, consisted of 431 mi. of line operated at 60 cycles in the eastern part of the state and 186 mi. operated at 30 cycles in the western part of the state. All 60-cycle lines are electrically connected through the busses at the station except the Jackson-Battle Creek section, this being isolated from the remainder of the system by transformers at Battle Creek. The 30-cycle lines are all connected. The two systems are interconnected through a 15,000-kv-a. frequency changer at Battle Creek. Sections shown by solid lines are those that were closely inspected and are referred to in the data in this paper. Those sections shown by broken line were put into operation prior to 1915 and were originally

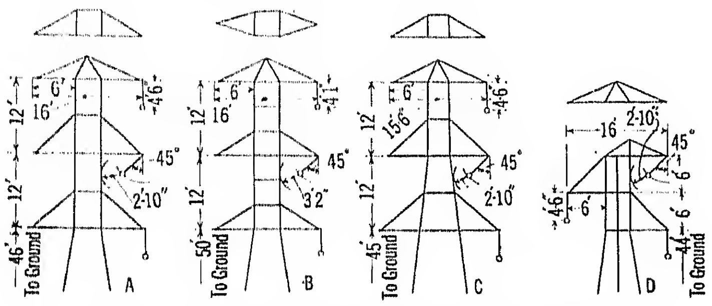

Fig. 4—Types of Towers Showing Dimensions and Clearances

equipped with the older type cap and pin insulators, quite a large number of which have since been replaced. The shuffling of the insulators in replacing the defective ones made it impossible to obtain satisfactory comparative data on these sections. Capacities of generating equipment totaled approximately 225,000 kv-a. feeding into the 60-cycle system and 100,000 kv-a. into the 30-cycle system in 1925.

Fig. 4 shows the types of construction conductor clearance and separation, height of tower, and other details of construction. There were no ground wires installed on any part of the system at that time, and one circuit was in place on the towers in all cases. The lines are equipped with Ohio Brass No. 25622 insulators.

Results of Inspection and Investigation

The inspection data cover a total of 305 mi. of line scattered throughout the state. The period of operation of the different sections varies from two to ten years. The country over which the lines are built is very flat, the maximum variation in height over any section being less than 200 ft. Therefore, the lines follow closely the contour of the ground.

Laboratory measurements by Peek[4] indicate that the voltage due to lightning storms in the delta-connected system such as this would be slightly less than in systems operating with the neutral grounded, all other factors, of course, being equal, and this is also borne out by comparison with the experiences on systems of the other type, so it would seem that these data should be fairly representative of results that might be obtained in other locations under similar conditions in so far as the number of flashovers are concerned.

Table I gives some additional construction details and a summary of the number of cases found where flashovers had occurred, their location on the tower, extent of damage to the line conductor, and other information. A study of this table shows some rather interesting conditions.

Rather wide variations in the results on different sections will be noted. The Junction-Grand Rapids, Mio-Loud and Loud-Emery Junction lines of very similar construction and not equipped with arc protection show a variation from 0.17 to 0.65 flashover per mile of line per year after 8, 10, and 9 years operation respectively.

The popular reason for this would be the variation in the severity and frequency of storms in the two localities. It is a fact that the Junction-Grand Rapids line runs north and south directly across the path of a great many storms as they pass inland off Lake Michigan, but on the other hand the Mio-Loud line follows very closely the bed of the Au Sable River, nearly east and west and lies parallel to the course of a great many storms which it is said by many have a tendency to follow the water courses. Possibly these factors may influence the results one way or another, but other conditions peculiar to the different lines may perhaps have a very decided influence on the operating results that have been obtained.

Height of Line Above Ground Soil Conditions, Ground Wire, and Other Factors

Measurements and tests made by Peek[5], have shown (a) that the voltage gradient between cloud and earth in the air under a storm cloud is approximately 100 kv. per ft. under severe conditions, and (b) that the voltage induced in the transmission line will vary with the height of the line above the ground, amounting to 30 to 50 kv. per ft. depending upon the closeness of the storm to the line and other factors. Also that placing a ground wire above the line reduces the lightning disturbances from 30 per cent to 50 per cent. The induced voltage, where the wires are placed in a vertical plane, should therefore be lowest in the conductor nearest the ground and correspondingly high in the other conductors.

The data showing the number and per cent of flashovers occurring on the top, middle, and lower conductors in Table I check quite closely with this law. There are some slight discrepancies, as on the Mio-Loud and Loud-Emery Junction lines, and in some cases flashovers

occur on the middle and lower conductors and not on the top wire, but in general, agreement is noted. There is, however, quite a wide variation in the results in this respect between the individual lines. On the Edenville-Saginaw and Saginaw-Flint lines, equipped with flux controls, the percentages of flashovers on the middle and lower conductors are lower than on other sections of the line. This would tend to indicate that the flux control has raised the flashover voltage of the string to some extent, but not sufficiently to keep the lower conductor entirely free of flashovers. On the Edenville-Saginaw line, there was but one case of flashover on the lower conductor over the two-year period. The sphere-gap effect of the tubular horn used with the flux control may perhaps have some effect, together with the shielding effect of the control insulator.

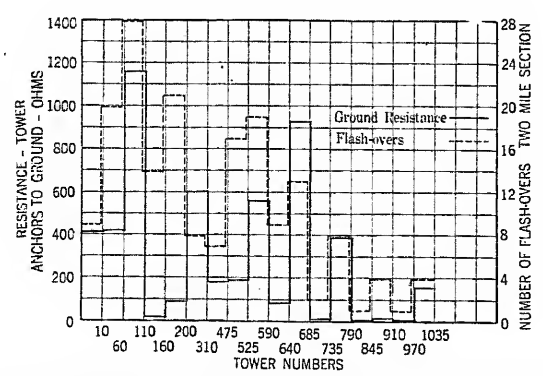

FIG. 5—NUMBER FLASHOVERS COMPARED TO GROUND RESISTANCE, JUNCTION-GRAND RAPIDS LINE

A comparison of the Edenville-Saginaw line with the Junction-Grand Rapids line shows a wide variation in this respect. The Junction-Grand Rapids line shows the smallest percentage of flashovers on the top phase, while the Edenville-Saginaw line shows the greatest with a wide variation over the three wires in spite of the higher nominal elevation of the conductors. In looking for other reasonable explanations for this difference, the possibility of soil conditions being somewhat responsible is suggested. The curves in Figs. 5 and 6 show a comparison of ground resistance measurements with the number of flashovers on the Junction-Grand Rapids and the Battle-Creek-Jackson lines.

The ground resistance was measured between the tower anchors (which are of the basket type) and ground rods driven into the ground approximately 24 ft. from the base of the tower. Complete resistance measurements of all the towers on the line were not available but at points approximately every five miles along the line, the ground resistance of several towers was measured. An average was calculated from each group, and from this data, the ground resistance curve was plotted. The broken line shows the number of flashovers occurring within one mile in each direction from the group of towers whose resistance was measured. That there is some relation between ground resistance and the number of flashovers seems apparent in the fact that both increase and decrease correspondingly with one or two exceptions which might be because of abnormal local conditions.

Peek[6] has called attention to the "water level" below the surface of the ground as being the effective ground level, and has stated that under equal conditions, an induced voltage is higher in dry sections because of the fact that the flux extends from cloud to water level, the effect being that of increasing the height of the line.

Referring to Fig. 5, it is noted that the ground resistance along the Junction-Grand Rapids line is very high, reaching a maximum of 1200 ohms. The soil along this line is very dry and sandy and in some small sections, it is almost devoid of vegetation. The country along this line is slightly more rolling in places than along some of the other lines, but not enough, apparently, to affect conditions to any extent. The high-resistance measurements were not confined to the higher points, but were found in all locations. The soil on the Edenville-Saginaw line represents perhaps the other extreme, being low and marshy with a considerable amount of heavy clay soil, and the water throughout this district is very salty; in fact, there are several chemical manufacturing plants obtaining their products from the brine pumped from the ground. A sufficient number of ground resistance measurements along the Edenville-Saginaw line were not available to plot a curve, but those taken indicate a resistance of not over four ohms.

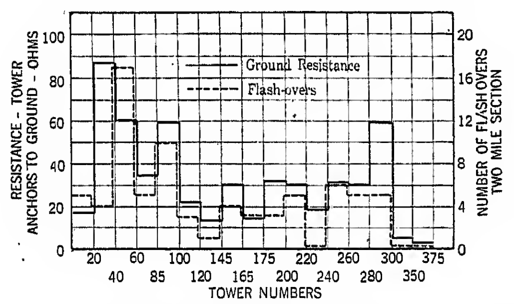

Fig. 6—Number Flashovers Compared to Ground Resistance, Battle Creek-Jackson Line

The conditions along the Battle Creek-Jackson line show lower ground resistance than the Junction-Grand Rapids line, varying between 10 and 100 ohms. The conductors being lower probably helped, but this was offset to some extent by the small arcing horns which probably increased the number of flashovers. The percentage of flashovers on the top conductor on this line is smaller than any other except Junction-Grand Rapids, and the other lines follow this trend, varying in proportion to the ground resistance. The location of the Mio-Loud line along the river probably helped to keep down the number of flashovers on account of the moist soil close under the line, also the triangular construction lowering the two top wires, undoubtedly helped to some extent.

With the increased effective height of the lines with higher ground resistance, all three of the conductors are well within the flashover voltage range and the effect of the difference in the height of each of the three conductors is proportionately smaller. On the Edenville-Saginaw line apparently the closer proximity of the lower wire to the effective ground level makes it almost immune to flashovers in spite of the higher nominal span. It also lowers the number of flashovers on the middle wire, but the height of the top wire raises it to within the range of the flashover voltage. The shorter strings of insulators on this line undoubtedly had some detrimental effect. Results of this kind suggest that the lines should be so constructed that all three conductors will be a minimum distance from ground or in a horizontal plane.

Comparison of the Junction-Grand Rapids and Edenville-Saginaw lines is of interest from the standpoint of the type of construction and possible effect of a ground wire. It is probable that if the Edenville-Saginaw line had been constructed with the horizontal configuration instead of its present form, this line would be very free from lightning trouble even without ground wires. On the other hand, the Junction-Grand Rapids line, with the same construction, would probably require one or more ground wires to produce equal results, and care would have to be taken that the ground wires were provided with a connection to water level or a good ground.

It has been supposed that flashovers might increase with the mileage of line, but the results on the Jackson-Battle Creek line, which is separated from the remainder of the system, does not bear out this theory and inasmuch as the lightning surges travel but a short distance, it is reasonable to believe that there would be no great difference.

Reports of operating results on lines in different sections of the country indicate quite a wide variation in results from the standpoint of trouble during lightning storms. In some cases, excellent results are obtained with but moderately insulated lines, and in other places, considerable trouble is experienced on much more highly insulated lines. It is apparent, however, that at least some of the conditions that cause these discrepancies are being cleared up, and before constructing lines in the future, the soil conditions and other factors not heretofore taken into consideration will be studied before the design is completed and more definite information obtained concerning the amount of insulation, number of ground wires, and other factors necessary to produce a line that will be as free as possible from these troubles.

Effectiveness of Arc Protection

Comparing the lines equipped with the flux controls and arcing horns with the others, the rather remarkable efficiency of the arc protection in reducing the damage to the conductor is noted. A decrease from 66 per cent, 38 per cent, and 24 per cent on the lines not equipped to

6. F. W. Peek, Jr., *Lightning and Other Transients on Transmission Lines*, A. I. E. E. Trans., Vol. XLIII, p. 1213.

3 per cent and 5 per cent on those equipped with arcing horns and 5.3 per cent and 11.5 per cent on those with flux controls is shown, the arcing horns being somewhat more effective than the flux controls. It will also be noted that there have been no failures due to burning of the conductor or insulator hardware on any line equipped with either type of horn which also emphasizes the advisability of providing some form of arc protection.

The conditions that were found on the Junction-Grand Rapids line with its 66 per cent of burns offer an excellent example of what may be expected of a line constructed in a locality of this kind without arc protection to the conductor or some means of holding down the lightning potentials.

It will be noted that the number of failures of the line due to the arc burning off the conductor, or some part of the insulator string at the time of the flashover, is rather small. There have been a total of only three in the eight years of operation on the Junction-Grand Rapids line and one on the Mio-Loud line. This, of course, is an excellent service record. However, of the 345 cases of damage found on the Junction-Grand Rapids line, a great many were so serious as to necessitate immediate repairs. Where the damage is not so great, there is, of course, some weakening of the conductor. This creates the hazard of failure at some future time when abnormal mechanical stresses are imposed upon the conductor, such as during severe sleet storms, and some failures of conductors on this line during sleet storms that have occurred in the past are now suspected of having been at least partly due to this weakened condition of the wire.

Aside from the damage to the conductor, the arcs do not seriously damage the other equipment. In some instances the top or lower disk is broken, but there has not been a sufficient amount of this to warrant the installation of protective equipment at the top of the string. In most cases there is no damage apparent from the ground. The current in the arc on the isolated system is smaller than if the neutral were grounded, which undoubtedly helps to a considerable extent.

The arcs shift around to a considerable degree over the surfaces upon which they are playing. The theory has been advanced that the arc causes a separate burn with each half cycle. The appearance of the spots tends to bear this out. The small round burns are found to be deeper and more severe on the 30-cycle than on the 60-cycle system due apparently to the greater duration in each location at the lower frequency. Using the number of spots found as an indication of the length of time the flash over exists it is thought that a great many of the flashovers are of very short duration, considerably less than one second, others, however, hold longer and evidently are the ones that cause the more serious damage.

The data also show that there are quite a number of flashovers on towers where the insulators are in the strain position. In most cases, however, the breakdown occurs between the jumper loop and the tower and it is believed in some instances that the loop is not always at a maximum distance from the tower due to wind conditions or distortion of the conductor due to other causes. Consideration in this case is being given to the use of methods of holding the loop away from the tower at the maximum distance under all conditions.

In Fig. 7 an effort has been made to show the conditions found relative to the travel of the arc and the cascading of the insulator strings. A typical tower top with the location of the burns that were found on lines with and without arc protection is shown. The figures opposite the insulator string and tower show the percentage of burns found on the different pieces of equipment with reference to the total number of flashovers.

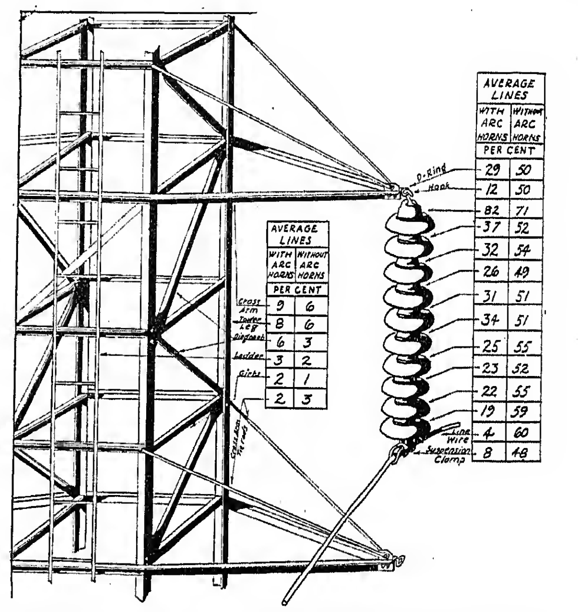

FIG. 7—RELATIVE LOCATION OF BURNS CAUSED BY FLASHOVERS

It is noted that in practically 50 per cent of the cases where no arc protection is used, the various caps of the insulators are burned. The number burned in each flashover varies, but the percentage of each is quite uniform over the total number of flashovers. The amount of cascading is not so great where horns are used varying from 19 per cent to 37 per cent on disks below the top one, but the amount of flashing to the tower basket is greater. This is particularly so with the flux controls and might indicate an effort on the part of the control to perform its duty of keeping the flashover away from the string. On the Junction-Grand Rapids line, about 15 per cent of the strings, where flashover had occurred, were found with all of the caps burned. On the other lines, however, this was of rare occurrence.

Fig. 7 shows again the very marked decrease in the amount of damage to the line conductor and clamp where arcing horns are used. These data are also of

interest in showing that a very high percentage of the flashovers occur over the insulator string and does not take place between the conductor and tower independent of the insulator string as has been thought.

The cascading and burning of the caps, except at the end of the strings, apparently takes place at the time of the initial flashover, as tests that have been made on various types of arcing horns show that there is a strong tendency for the power arc to blow away from the string in almost all cases, regardless of the type of arc protection in use. During part of the 1926 lightning season, there was a new line between Argenta and Battle Creek on the opposite side of the tower from the old one which had not been put in service and had both ends grounded. An inspection showed that several flashovers had occurred on this dead line and the caps show burns similar to those on the live lines.

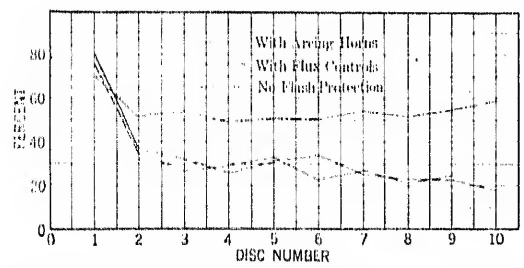

Fig. 8—Cascading of Insulators with and without Arc Protection

The curves in Fig. 8 also show the amount of cascading quite clearly on the lines with and without arc protection. The curves show the effectiveness of these particular types of arc protection in reducing the amount of cascading.

Measurement of Surges

Four klydonographs were in service on the system during the year 1925 and as indicated in Fig. 1, instruments were placed at Cooke, Shaftsburg, and Battle Creek on the 60-cycle system and at Grand Rapids on the 30-cycle system. These instruments were in service for a period of about eight months, which included the lightning season.

In Table No. II is a summary of the record of the four installations and shows that a total of 567 surges of between 1.5 and 10 times normal voltage to ground were recorded. It is noted that only the lightning surges reach values in excess of five times normal and are undoubtedly the cause of the insulator flashover. This checks closely with operating records inasmuch as flashovers occur during lightning storms and in localities where the storms are known to be present. With the klydonographs so widely scattered, these registrations can only be taken as a partial record of the number and magnitude of the surges due to lightning, as this type of surge is of steep wave front and is quickly attenuated. In one case the klydonograph at Grand Rapids registered 10 times normal voltage on one phase and nine times on the other two. The maximum surge recorded was during a severe lightning storm directly over the Cooke station. At this time the potentiometer, which was of the ring type, supported on post type insulators, flashed over from the top ring to the bottom of the insulator column. The klydonograph flashed over between all three terminals and to ground and produced a very large image across the film. It is thought that about 15 times normal voltage would be required to flash over the potentiometer so it is evident that voltages in excess of this were present in the transmission line.

The insulator strings themselves are perhaps the best indicator of the magnitude of the surges. Peek[7] has shown that the lightning sparkover of a string of suspension units such as used on these lines is between 1,200,000 to 1,400,000 volts. The results indicate that voltages of this magnitude or greater are present on the lines and also show the correctness of the use of a potential gradient of from 30 to 50 kv. volts per ft. in calculating the voltage that may be present in lines close to lightning storms.

The surges due to switching and arcing grounds are much less severe than those caused by lightning and in so far as the line insulators are concerned, are not of

TABLE II

7. F. W. Peek, Jr., *Lightning and Other Transients on Transmission Lines*, A. I. E. E. Trans., Vol. XLIII, p 1215-16.

great concern. Undoubtedly the registrations made by them are nearer to their true value than is the case with lightning surges, as they travel greater distances along the line.

The records covering the klydonograph installations at the different locations did not vary to any great extent although the instrument at Grand Rapids recorded a greater number of more severe lightning surges than the other instruments which undoubtedly is consistent with the other flashover data, as this instrument was connected to one end of the Junction-Grand Rapids line where the most severe conditions are thought to exist.

Relay Protection

The relay scheme in use has not been shown. This has been developed along with other parts of the system over the period of years covered by these data, but in general it consisted of the usual standard relays.

In 1926 a system of ground relays operated by the unbalanced residual current in the line when a ground occurs was installed on the 60-cycle system and very good results have been obtained[8].

We have been unable to connect up all of the flashovers with surges or disturbances on the system, and it is thought that in many cases the arc extinguishes itself without starting a disturbance that would cause surging in voltage or circuit breaker operation. This is perhaps another peculiarity of the isolated system.

Insulating and Arcing Devices

Assuming that the lightning sparkover voltage of the insulator string varies with its length, it is apparent that there is an advantage in increasing the length of the string provided sufficient clearance is maintained from other parts of the structure. Insulators of rather close spacing are in use in a great many instances. One object is to reduce cascading as much as possible; also to reduce the stress across the individual units. The data on this system, however, indicate that even with a very closely spaced unit the cascading takes place. With the improvements that have been made in insulators during the past few years, the danger of puncture is much less than heretofore, so that it would appear that there is considerable gain in protection to the line from lightning flashovers as well as from the cost standpoint in using the wider spaced unit in obtaining a longer string.

In sections of the country removed from the sea coast and where trouble from fog or dust is not experienced, the use of wooden pole structures in the place of steel towers appears from the insulation standpoint to have some merit. Advantage is taken of the insulation of the wooden structure which apparently is considerable, and in certain locations like in the vicinity of the Edenville-Saginaw line, wood pole lines with the conductors carried in a horizontal plane at the minimum distance from the ground might provide a line that would be very free from lightning trouble, without the use of ground wires.

The choice of an arcing attachment for the insulator string is somewhat of a problem. Various kinds of horns and rings are offered. Some are said to be more efficient than others in not only protecting the conductor and insulators from the arc, but bettering conditions around the insulator string so that the flashover is not so apt to occur. Experience on this system has been confined to the types of horns shown in Figs. 2 and 3 and has demonstrated the high efficiency of the small arcing horn as protection to the conductor, but which, like all plain horns, undoubtedly lowers the flashover of the string. Systems where more severe arc conditions exist might not obtain as good protection and would have to consider their own local conditions. There does not appear to be any marked difference in protective value between the various kinds of plain horns. The power arc has a strong tendency to blow out away from the insulators in most cases, but devices that will prevent the cascading of the string at the time of the initial flashover might be of considerable value.

Remedial Measures

Ground wires are being installed on all tower lines now under construction on this system and are either being installed or contemplated for at least part of the older sections of the system.

On the Saginaw-Flint line, which has been completed for two years, a ground wire will be in place during the 1927 lightning season, and it is planned to secure data showing the effectiveness of this ground wire in reducing flashovers. There is a second line between these two places, shown on the map with a separation from two to eight miles, which has also been carefully inspected to determine its present condition in regard to flashovers. A number of surge recorders of the klydonograph type will be placed at frequent intervals along both of these lines and it is hoped to get a good comparison between the two lines with and without ground wire.

Ground resistance measurements are being made over a number of other lines with the idea of determining more definitely the effect of soil conditions and the location of the effective ground level and to determine the necessary protective equipment for future and also some of the present lines. It is planned to install arc protection of some type on all of the lines whether or not ground wires are installed, as it is evident there will still be a number of flashovers in spite of the equipment installed to reduce the disturbance caused by lightning.

Consideration is also being given in some locations to use of the wooden pole "H"-frame construction as a means of increasing the insulation of the line and placing the conductors in a horizontal plane as close as possible

8. *Directional Ground Relay Protection of High-Tension Isolated Neutral Systems*, Breisky, North, and King, Summer Convention, A. I. E. E., Detroit, Mich., June 20-24, 1927.

to the ground. It would seem that this type of construction would give the maximum protection in so far as the lightning storms were concerned, provided some method is worked out to prevent the shattering of the poles and crossarms and the possible burning of the poles or crossarms in some localities due to leakage over the insulators.

Conductor clearance and separations have been increased on all new lines, and provisions made for the installation of longer insulator strings, if this seems desirable after the effectiveness of the ground wire has been determined.

On the strain type construction some means of holding the loop or jumper will be installed so that there will be no possibility of its coming close enough to the tower to cause flashovers.

Conclusions

1. Transmission lines in sections where lightning storms are prevalent are subjected to extremely high voltages, which will cause quite frequent flashovers of the insulators unless constructed in such a manner, or protected so as to hold down this voltage.

2. The severity of the conditions affecting the line varies considerably in different sections due to local surroundings and perhaps the severity of storms.

3. Unless equipped with some type of arc protection, damage is very apt to result to the line conductors, which, if it does not cause failure at the time, weakens the wire and creates the hazard of failure at some future time.

4. Cascading of the arc over the insulator strings will take place to some extent in nearly all flashovers unless the string is provided with suitable preventative equipment.

5. Surges due to switching or grounds in so far as the line insulators are concerned do not appear to be of serious consequence.

6. Careful inspection of lines is warranted on account of the defects found that are not apparent from the ground, particularly on a system operating with isolated neutral.

7. It seems desirable that a thorough study, including conditions affecting the height of line, as well as the frequency and severity of storms, be made before a line is constructed to determine the necessary protective features.

Discussion

G. H. Doan: The top wire of our 120-kv. lines is very much more susceptible to flashover and damage than any of the others. We had concrete evidence of that last year when a lightning stroke hit directly on a radio tower which was very close to the high-voltage lines. A klydonograph about a quarter of a mile away showed that there was about 5 times normal potential on the top wire, 3.3 on the middle, and 2.7 on the bottom. That, however, did not cause flashover, and did not, of course, cause opening of the oil circuit breaker.

This is further borne out by the position of broken insulators. The record for last year shows that 77 per cent of the insulator flashovers were on the top wire, 19.4 per cent on the middle, and only 2.8 per cent on the bottom wire.

We have also some very interesting data as to the good of ground wires. We started our 120-kv. system, and ran it during the season of 1925 without a ground wire on that portion which was working. During that season, we had 114 automatic switch openings. During the winter it was equipped with a ground wire, and the following year (in 1926) we had 7 openings, which is a reduction in switch openings of practically 94 per cent. The storms which passed over that area decreased 47 per cent, so that there is a possibility that the storms which we had were not so severe, and we certainly know we didn't have as many of them; but it seems that the ground wire had afforded quite a little protection.

Mr. Hemstreet points out that in dry sandy country he has experienced many more flashovers than in the lower districts. We also find that is true. In one particular section, where the land is rather high, rolling, and sandy, and the ground resistance rather high, we have experienced, I think, about 50 per cent of the flashovers of which I spoke.

R. L. McCoy: Mr. Hemstreet has pointed out the advantage of the longer-spaced suspension insulator. It has always been the policy of the Locke Insulator Corporation to recommend the use of a relatively long-spaced suspension unit.

A few years ago the major insulator problem was that of preventing puncture of the units by the voltages impressed upon them. That problem is now well in hand and the major problem is to prevent lightning flashovers as much as is possible and feasibly economical and to prevent the attending damage.

Researches which have been made by Mr. F. W. Peek have shown us the nature of the voltage impressed upon line insulators by lightning.

It is desirable that we study the action and characteristics of line insulators under these voltages. The lightning generator has given us an opportunity to make these studies. A very careful investigation has been made with lightning. We find that with all types of suspension insulators regardless of the spacing, cascading occurs. This fact is borne out by Mr. Hemstreet's experience.

The reason for this is found in the fact that the distribution of the voltage impressed on the various units of the insulator string is not uniform. The line unit bearing the brunt of the surge flashes over before the remaining insulators flash over. This, then, makes the second unit from the line at the same potential as the line and it flashes over. The flashover therefore is progressive, one unit at a time, with the arc striking to each insulator cap. The power arc follows the path of the lightning arc and starts as a pure cascade. This accounts for a large number of cases where we find cascading on all of the units of an insulator string when it was flashed over by lightning. Incidentally, we find this on insulators of all spacings.

Our problem then is to find a way of using the insulation in the insulator to the best advantage to produce high flashover values which will reduce number of flashovers, and prevent cascading of the lightning arc. Recent studies with lightning show no appreciable difference in cascading between insulators of minimum spacing and insulators of approximately 6-in. spacing for a 10-in. disk.

Flashover values are directly in proportion to the string length. The longer spacing is obviously advantageous from this point of view.

Mr. Hemstreet states further that the power arc has a strong tendency to blow away from the insulator if the initial cascade caused by lightning can be prevented. The grading shield offers a means of doing exactly this. The reason for this is that the grading shield reduces the voltage across the line unit and makes the voltage duty upon each unit more nearly uniform and when the flashover occurs it is a complete flashover from ring to ring, or, ring to horn, and the arc is started several inches away from the insulator. The chances of its doing damage therefore are much reduced.

Recent investigations show that the grading shield can be designed to prevent cascading of the lightning arc, and also because of better field conditions established, give an increase of from 15 to 20 per cent in the flashover value over that of the unprotected string. This is interesting, because on 132,000 volts or above we are near the point where the insulators have a flashover value equal to the voltage imposed upon them. An increase,

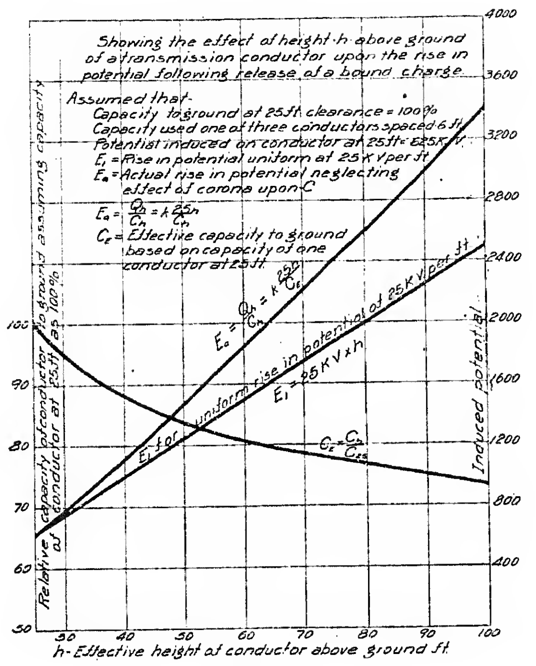

FIG. 1

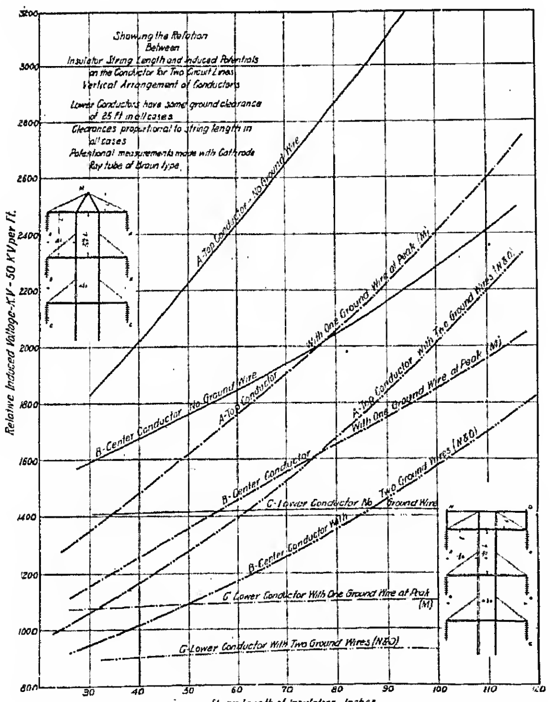

FIG. 2

therefore, of a few per cent in the flashover value may reduce very materially the number of flashovers.

A. O. Austin: In view of some of the points raised by Mr. Hemstreet's paper, it would seem that some recent theory and investigation should be of interest.

Flashovers on transmission lines are reduced by raising the effective flashover voltage of the insulator between conductor and ground, or by reducing the abnormal potential on the conductor. In addition to these two methods or factors, a new method has been developed which I have called the counterpotential method.

In this discussion I wish to call particular attention to the last two methods.

The new method eliminates the danger of burning and permits taking advantage of the very high flashover values for lightning possessed by wood structures, to which Mr. Hemstreet called attention.

Reduction in the effective height of the conductor and the installation of ground wires are two factors which can be used to advantage for increasing the ratio of flashover voltage to surge potential for steel tower lines. Recent improvement in the theory of the ground wire gives a working knowledge of the

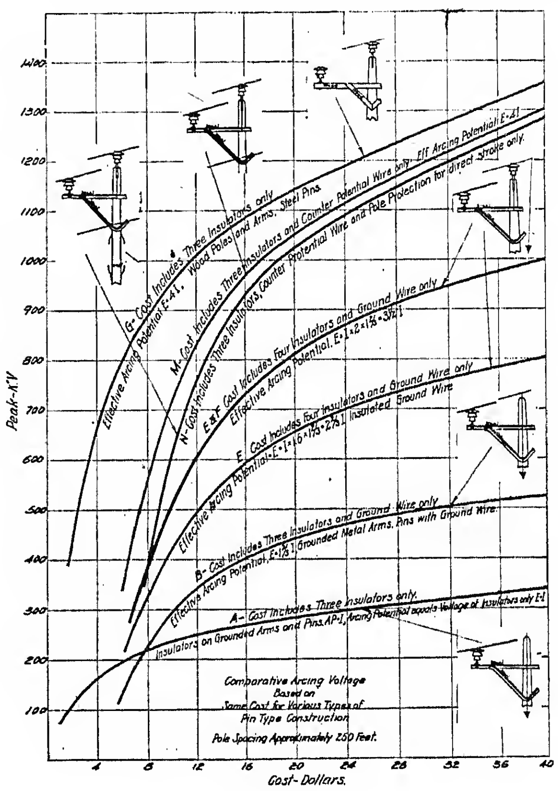

FIG. 3

various factors governing its functioning so that it can be evaluated for any installation. In applying the ground wire, to obtain best results, it is necessary that we have a knowledge of just how it functions.

A charged cloud over the power conductor will induce a charge on the conductor. This charge is a bound charge and will be the same for a conductor or a ground wire in the same position. Following the discharge of the cloud, the bound charge will be released and cause the potential of the conductor, if insulated, to rise. This rise in potential is of great importance and a study of the factors has been made. Before the cloud discharges, the conductor may be regarded as forming a condenser with the cloud. Following the discharge the conductor forms a condenser with ground or objects of lower potential such as a ground wire. In general, the potential on a conductor may be said to vary as Q/C where Q is the charge and C the effective capacitance of the conductor to ground. It therefore follows that factors which affect Q and C must be given consideration in determining the rise in potential for a given gradient.

The charge Q will increase directly with the height in a field of uniform gradient while the value of C is reduced with the height of the conductor. It therefore follows that the induced potential Q/C will increase at a more rapid rate for greater heights of conductor. This is shown in Fig. 1 herewith.

Bringing the power conductors nearer together reduces Q, but this advantage is partially offset since it also reduces C. Where a ground wire is used to increase C, it is evident, however, that close spacing reduces Q and increases C. Since the ground wire functions by increasing C rather than by reducing Q, its location and number should take this into account rather than its location for screening.

By the use of a cathode ray oscillograph of the Braun-tube type it is possible to measure induced voltages on model lines with ease.

Fig. 2 shows a study based on string length. In this study the induced voltage on the conductors of a two-circuit line is shown as measured by this method. It will be seen that the induced potential rises very rapidly with the increase in string length. Increasing the length of a string 2 ft. not only spreads the conductors but raises the top conductor at least 10 ft. Where the electrical gradient set up by the cloud is steep, it is seen that increasing the string length may result in more flashovers unless the height of the conductors is kept down or the factor C increased by placing ground wires at other points than at the peak of the tower.

In wood-pole structures the problem is different. The installation of a ground wire may eliminate insulation several times that of the insulator. It therefore follows that where a ground wire is usually an advantage on a steel-tower line, it almost invariably increases line trouble when applied to a wood-pole line which has effective insulation. The reasons for this are clearly shown in Figs. 3 and 4. It will also be noted that the insulated ground wire and the counter-potential wire have great advantages over the ground wire for preventing flashovers induced by lightning. While the insulated ground wire cannot be used where unbalanced leakage is likely to burn the pole, the counter-potential wire takes care of this and also facilitates the operation of relays.

The counter-potential wire may be very effective when applied to a steel tower having an insulating zone. In operation, the release of a bound charge raises the potential of the counter-potential wire and connected tower top or cross arm coincident with the rise in potential on the power conductor. Since the potential of the insulator support is raised, the stress tending to that flash the insulator or conductor will be reduced by the amount the tower top is raised by the counter-potential or charging wire.

By properly spacing the height of the counter-potential wire it is possible to control the potential of the support adjacent to the insulator so that the flashover voltage of the insulating zone of the tower can be added to that of the insulator, giving exceedingly high flashover values for what would otherwise be a low or moderate flashover voltage system. In addition to giving exceedingly high flashover values it makes it possible to effect very material economies due to the closer spacing of conductors.

Since the danger of burning of the insulated section is removed by the counter-potential wire and relay operation is insured, this new method of line construction has material possibilities which may be applied for improving old lines as well as being adapted for new construction where it is desired to reduce or eliminate flashovers.

It is also possible to use the construction in conjunction with a ground wire. It is, however, necessary to place the ground wire below the insulated zone or to insulate it from the upper section of the structure.

Mr. Hemstreet raises the question as to the effect of ground

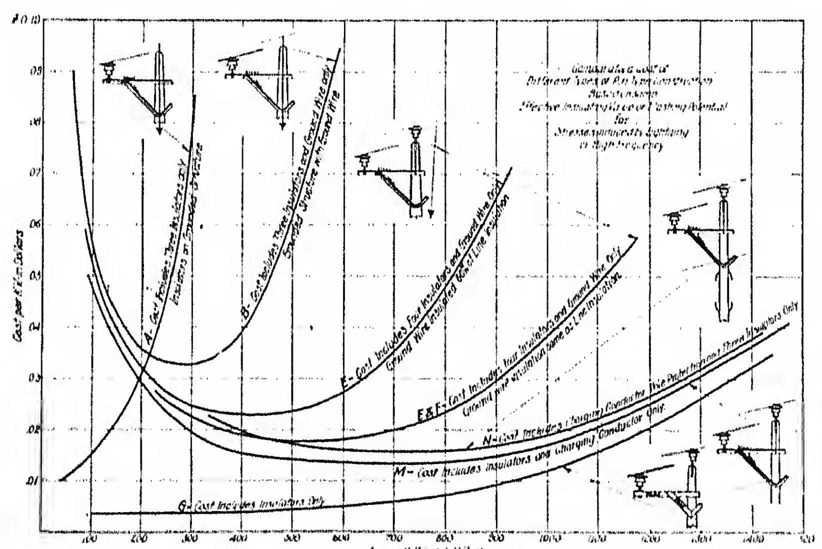

FIG. 4

resistance on flashovers. From a consideration of the counter-potential wire it is apparent that if the effective height of the conductor has not been increased, a high ground resistance may permit the structure to be charged momentarily. This will tend to reduce the stress tending to flash the insulator so that the danger of arcing would really be less. If the nature of the ground, however, is such that the conductors have a very high effective height, this may more than offset the high ground resistance and result in increased flashovers.

Impact tests made recently on long strings with much larger amounts of energy than have heretofore been available, show that many insulator strings or arrangements which it has been assumed (from tests on short strings), would arc free, frequently cascade. These tests apparently give results similar to those shown in the examination carried out by Mr. Hemstreet. It is hoped that an oscillograph record of the flashovers on test will throw much light on the nature of some of the various types of flashovers noted on the system.

While the path of an arc may be determined at the expense of flashover voltage, once formed further control of the arc is lost, hence operation can best be improved by increasing the effective ratio of flashover voltage to the surge voltage. With a better understanding of the various factors it is now possible to consider the cost of the line per mile on a flashover basis as well as on a mechanical basis. When this is carried out, great improvement in the elimination of flashovers will result.

W. L. Lloyd: I am glad to note that the operating results have checked so well Mr. Peek's laboratory tests, in that the lightning voltage is directly dependent upon the height of the phase wire above conducting soil.

With wet soils, the greatest number of flashovers should occur on the upper conductor. I understood Mr. Hemstreet to say that actually 85 per cent of the flashovers occurred on the upper conductor under such conditions, whereas the lower conductor was practically immune from lightning.

With dry soils, where the conducting level is perhaps far below the ground level, and the percentage difference between the effective heights of the three vertically spaced conductors is greatly diminished, there should be more flashovers; but a more even distribution in the number of flashovers should be expected. This is in accordance with the operating results reported by Mr. Hemstreet.

On important lines, we recommend the ground wire to reduce the number of flashovers and the grading shield to eliminate damage to the insulator string or line conductor in the case of those fewer number of flashovers which remain.

I am particularly interested in the klydonograph surge-recorder measurements on this system, and am glad to note that these measurements check so well with our estimates based upon tests in the laboratory with Mr. Peek's 2,000,000-volt artificial-lightning generator.

J. G. Hemstreet: It is gratifying and encouraging to know that the representatives of operating and manufacturing companies and those working in the laboratories on this same problem are in agreement on practically all of the various points that have been brought out.

It is evident that a great deal of the mystery surrounding the transient conditions existing in transmission systems is being cleared away and the knowledge that has been gained of these conditions from experience in the field and laboratory tests and investigations may enable us to provide high-voltage transmission lines that will be very free from trouble due to lightning.

Mr. Austin has introduced somewhat of an innovation in the counter-potential method of preventing insulator flashovers. Results of experience in the field will be awaited with interest to determine if this method is as effective as a ground wire. One of the benefits obtained from the use of ground wire is the protection to the station equipment by holding down the transient voltages in the transmission line. The counter-potential method evidently does not accomplish this purpose, but possibly a combination of the two using ground wire near the stations might accomplish the desired results.

Ground Relay Protection for Transmission Systems

BY B. M. JONES[1] and G. B. DODDS[1]

Member, A. I. E. E. Non-Member

Synopsis.—*The relay problems of an electric power system are most important, and are very vital to the successful operation of the system. More and more consideration is being given to the relay engineers' point of view with resultant improvement in system operation. Several large, successful companies undertake no project having any bearing on the primary electric system without due regard to the relay engineer's recommendation.*

With the transmission networks becoming more and more interconnected, and with the injection into the problem the interconnections with other power companies, the absolute necessity of isolating a faulty line, (or a faulty piece of equipment), is essential and is becoming more clearly recognized by all large companies.

Since this article was written, other 66-kv., ground relay tests have been made with a resistor grounded neutral and with a solidly grounded neutral, and some very interesting and unexpected points were discovered. It is hoped these points will be brought out during the discussion of this paper.

* * * * *

THE question of ground protection has always been a serious one and also a very troublesome one. In the days when transmission systems were operated with a free or floating neutral and one leg of a line became grounded, this would throw a high potential on the other two legs and thus subject the lines and equipment to an unusual strain and possible damage. It would also endanger the lives and safety of people who might come in contact with the grounded line. To locate such a ground in a network was a very hard thing to do and often resulted in outages to a great many customers in the process of finding the line with the fault on it.

The subject of ground relaying is becoming more important, and is attracting more attention in the operation of light and power systems. It is considered absolutely necessary to isolate a grounded line immediately, for several reasons:

1. To reduce chance of injury to people who may come in contact with or approach a grounded line, thereby encountering dangerously high ground potentials,
2. To reduce the resultant damage to apparatus and lines by removing a ground as quickly as possible from the system.

On systems using overhead construction on wooden cross-arms, the ground currents encountered are relatively small and very sensitive ground relays are required to recognize these small currents.

As a result of the troubles encountered with an ungrounded system, a great many companies now make a practise of grounding their transmission system. The grounding of a system may be done in a number of ways, which are shown in Fig. 1. Where the star point of transformers or generators is brought out, this point can be grounded, either solidly or through a resistance. When there is no neutral point available, a grounding transformer may be installed. Grounding transformers are usually connected either star-delta, with the star point grounded, or zigzag, with the star point grounded, both methods having their particular advantages depending upon the particular application.

When the star-delta grounding transformer is used,

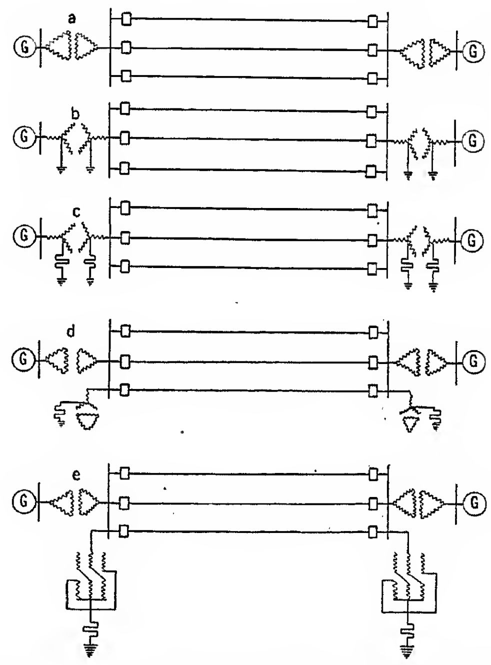

FIG. 1—METHODS OF GROUNDING TRANSMISSION SYSTEMS

a. Early ungrounded systems
b. Solidly grounded systems
c. Resistor grounded systems
d. Star-delta grounding transformer banks systems
e. Zigzag grounding transformer banks systems

the star point may be grounded either solidly or through a resistor. If desired, a load may be taken from the delta-connected secondary of the transformer bank.. The advantage of the zigzag-connected grounding transformer bank is the relative cheapness of it, since with it no secondary winding is required and thus it is somewhat cheaper than the star-delta bank.

1. Duquesne Light Company, Pittsburgh, Pa.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

Where the system is solidly grounded, the relaying for ground faults is comparatively simple if the fault current obtained is greater than the load current. In some cases, however, the current for ground faults is comparatively small, due either to long transmission lines or to contact resistance at the point of the fault. Where this condition exists, the phase relays will not protect the line for ground faults, and other means of protecting the lines for grounds must be used. It is nteresting to note in this connection that some companies with very long high-voltage transmission lines protect these lines against ground faults only.

On systems which are grounded through a resistor in the transformer bank neutral, the relaying for ground faults is somewhat involved, due to the small ground currents obtained and, in the case of a network, to the distribution of this current through several sets of lines and relays.

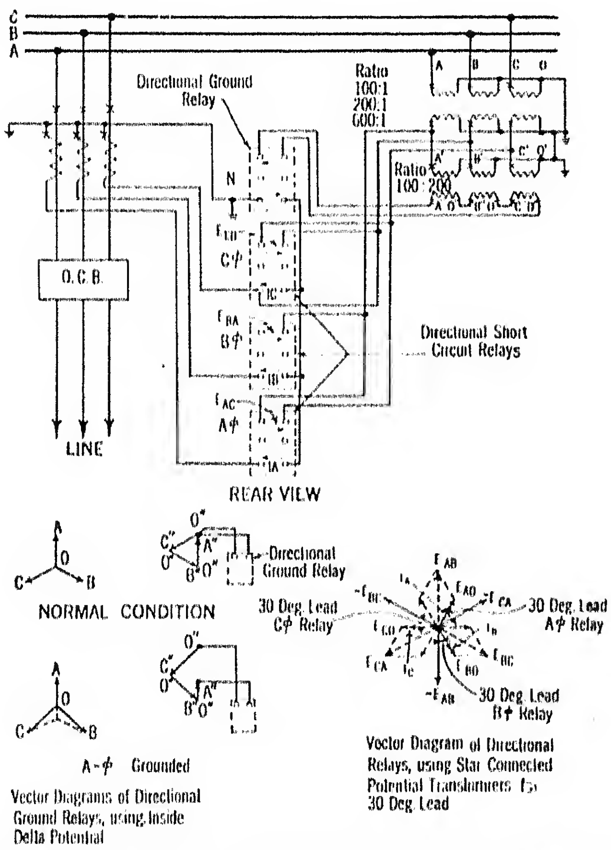

Fig. 2—Directional Short-Circuit and Directional Ground Protection

Many different schemes for ground protection have been devised, some of which are indicated below:

1. Overcurrent non-directional relay in neutral of current transformer circuit,
2. Overcurrent non-directional relay interlocked with directional elements of phase relays,
3. Power relay with instantaneous time but interlocked with overcurrent non-directional relay for timing,
4. Power relay with self-contained timing element,
5. Impedance ground relay,
6. Power directional relay using inside delta voltage,
7. Balanced current ground relays for parallel lines.

The overcurrent non-directional ground relay is satisfactory for use on radial feeders or other locations where directional protection is not required, such as bus or transformer differential protection, or on radial lines. In connection with such uses, a relay with a low operating range and one which puts a small volt-ampere burden on the current transformers is very desirable and has been developed. This type of relay is very sensitive to small ground fault currents and, due to its low volt-ampere burden, does not overburden current transformers which have other apparatus than relays connected to them.

The overcurrent non-directional relay with its trip circuit interlocked with the directional element of the phase relays was used quite extensively and proved fairly satisfactory in some cases. This type of protection, however, has one main inherent defect which is impossible to overcome. This defect is that on a single-line loop having more than one looped station and having a feed from both ends of the loop, a fault may occur which, while providing enough current to operate the ground relay, will not be of sufficient magnitude to overbalance the load current, with the result that the directional contacts on the wrong set of relays will be held closed and the wrong breaker tripped out.

The power relay has not proved satisfactory for ground protection, due primarily to the fact that a sufficiently low range relay has not been used. With this scheme, the power relay obtained current from the neutral of the current transformers and voltage from the inside delta voltage of an auxiliary set of star-delta connected potential transformers. With this scheme of ground protection and with a fault occurring some distance out on a line away from the substation at which the relays are located, the resultant voltage distortion at the substation may be relatively small, even though the fault currents be comparatively large. Under these conditions of fairly large ground currents and small voltage impressed on the power relay, in conjunction with the poor power factor which sometimes exists during ground faults, the resultant watts in the power relay may be so low that the relay will not operate at all or will operate very slowly. Due to this condition, the possibility of clearing ground faults in a minimum time is decreased.

The low energy power directional ground relay using inside delta potential is one of the most satisfactory schemes. A diagram of connections is shown in Fig. 2. In this scheme the same potential is used as was used in the power relay, but it is used only to operate the directional contacts of the relay, the relay having a separate overcurrent element similar to that of the overcurrent relay. The overcurrent and directional contacts are connected in series as in other power directional relays. In this type of relay, the timing is obtained from the overcurrent element. By using

this scheme, the directional elements may be made to operate on a very small number of watts, thereby making it sensitive to very small ground currents. An installation of this type of protection is shown in Figs. 3 and 4, which views were taken in a small substation on a consumer's property, there being one 22-kv. line looped through this station. Fig. 3 shows the front

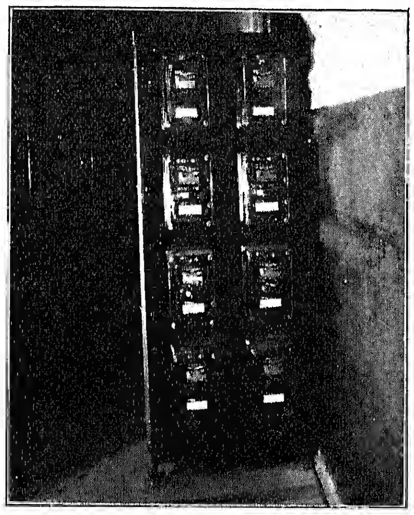

FIG. 3—FRONT VIEW OF CONSUMER'S RELAY INSTALLATION

view of the relay panel and Fig. 4 shows the rear view of the panel with the auxiliary star-delta connected potential transformers, and also shows the individual relay test switches for each relay.

The impedance type of relay has been used with reasonable satisfaction on systems which are solidly

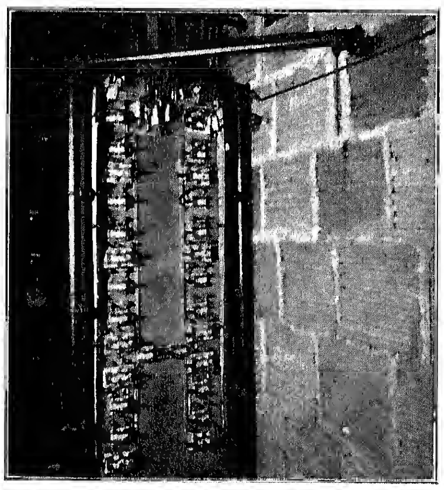

FIG. 4—REAR VIEW OF CONSUMER'S RELAY INSTALLATION

grounded. These relays may be self-contained, in which case one per phase, or three for a three-phase line, will be required, or the double-element phase and ground relay combined in one case may be used. These relays may obtain their potential direct from the line potential transformers or may use low-tension potential through compensators. The ground impedance relays have the same time characteristics as the phase impedance relays, thereby clearing faults close to the station in a short time and increasing the time for faults farther away from the station. These relays are not so satisfactory, however, for use on a system which is grounded through a resistor, since the voltage drop is usually not large enough to cause the impedance type ground relays to operate in a reasonably short time.

The balanced current type of protection is limited in its application to parallel lines. It furnishes a simple and fast method of clearing all ground faults and is an inexpensive method, for no potential transformers are required. The station must have two sources of feed, however, and when one of the pair of lines is out of service, an extra set of relays is sometimes required in order to permit increased time of operation to obtain selective action with other stations. This type of protection has been described in detail by Mr. H. P. Sleeper.[2]

There are several methods of checking the current and potential phase relations on the ground relays in order to determine whether the relay will operate correctly under fault conditions. Among these methods may be mentioned the following:

1. By using phantom load,
2. By using actual load,
3. By actually placing a ground upon the line.

The Duquesne Light Company, along with several other companies, is strongly in favor of the latter method of checking the direction of the ground relays, having found by sad experience, when using the first two methods mentioned, that mistakes and errors are very liable to occur, with the result that under actual fault conditions, improper relay and breaker operations result.

In connection with the checking of ground relays by actually placing a ground on the line, some very interesting results have been obtained, among which is the relation of ground current to phase voltage with different amounts of resistance in the high tension transformer bank neutral.

This point was brought out very forcibly during some tests conducted by the Public Service Electric and Gas Company of New Jersey which were made in July 1926. A tabulation of their test data is shown in Table I. An analysis of this data shows that with no resistance in the transformer bank neutral, a phase angle of around 90-deg. lag is obtained, and with a resistance of 75 ohms in the transformer bank neutral, the phase angle varies from 5-deg. lag to 15-deg. lag, while with a resistance of 300 ohms in the transformer bank neutral, the power factor ranges from unity to 18-deg. lead. As a result of the poor power factor obtained under conditions of the transformer bank neutral being solidly grounded, the resultant torque on the relay

disk is very small, even though the fault current be relatively large, and if the phase angle is greater than 90-deg. lag, the direction of operation of the relay will be reversed.

Similar tests were conducted by the Duquesne Light Company during May of 1926, in order to determine the following points:

1. To determine the minimum amount of ground current on which the 50-watt power relays would operate,

2. To make an actual check on the direction of operation of the power ground relays,

3. To determine the effects of putting more than one potential element of the ground relays in parallel on the same set of auxiliary potential transformers,

4. To determine the sensitivity of the low-energy power directional ground relays as compared with the 50-watt power relay.

The test data are shown in Table II and the conclusions arrived at are as follows:

1. The power relays set on a 50-watt tap would not operate satisfactorily with less than a 300-ampere ground, the ground being located at the substation at which the relays were installed. As the ground location would become farther away from the substation, the ground current necessary to operate the relay would become higher, due to less voltage being impressed on the power relay.

2. The direction of all ground relays tested was found to be correct.

3. The addition of an increased number of potential elements of ground relays to one set of auxiliary potential transformers did not result in any noticeable drop in voltage on the secondary of the auxiliary potential transformers. This indicated that the auxiliary potential transformers could be loaded up to their volt-ampere capacity.

4. It was found that the low-energy power directional ground relays would operate satisfactorily on a much lower ground current than the power relays.

Since the above tests were made, low energy power directional ground relays have been installed on the majority of the lines of the Duquesne Light Company 22-kv. system, and a large number of these relays has been tested by actually putting grounds on the lines which these relays protect.

The equipment used in making the line ground tests is shown in Fig. 5. Fig. 5A shows a two-ton trailer on which the necessary equipment for making high-tension line ground tests is mounted. Fig. 5B shows the water rheostat set up and connected to the line. Fig. 5C shows the water barrel emitting flame during line ground tests made at night. Night testing is sometimes necessary due to being unable to obtain the necessary outages during the day. The grounding is done by connecting a water rheostat between the line and a ground connection. The rheostat consists of a barrel inside of which is one fixed and one moveable brass plate. The ground current obtained can be varied by changing the distance between two brass plates im-

mersed in the water. The ground lead is connected to the fixed brass plate and brought out through the side of the barrel. A current transformer is connected in this ground lead and is used for measuring the ground current.

This equipment is all mounted on the two-ton trailer which is hauled from place to place by a truck. The equipment consists of the following:

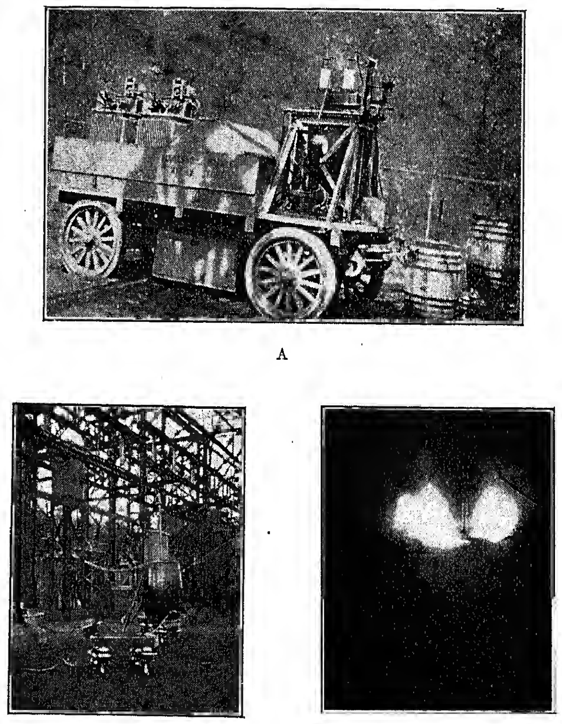
1 37-kv. single-pole oil circuit breaker,

1 30-cell, 60-volt battery,

1 Portable control panel with flexible leads 50 ft. in length,

2 Water barrels to be used as rheostats,

1 Water barrel for water supply,



A

B C

c. High-tension line ground tests made at night

2 Insulated stands on which to place the water barrel rheostats,

2 220-volt regulators,

3 Tool boxes for equipment,

3 Current transformers having the following ratios, 500 to 5, 400 to 5, 200 to 5,

3 12-volt flood lights,

Assorted leads of "00" flexible Tyrex single-conductor cable,

Assorted clamps of different types,

A number of pillar type insulators,

First aid box,

Fire fighting equipment,

Blocks and tackle.

The above equipment is all carried on the trailer and provides all of the equipment necessary for conducting grounding tests with the exception of portable meters which are not transported on the trailer but are obtained as required. An ammeter is mounted, however, on the portable control panel and is connected in the current transformer circuit of the grounding lead.

In connection with the testing of relay installations by actually placing faults on the lines, it may be remembered that a paper was presented at the A. I. E. E. Spring Convention held at Pittsburgh during April, 1923.[3] In this paper was described in detail the testing of the relay installations by putting faults on the 66-kv. line.

As a result of the experiences of this and other companies, it is believed that the inside delta power directional ground relaying is the most reliable and satisfactory type of ground protection that can be used on a system having a resistance in its neutral circuit. On systems which are solidly grounded, other types of ground protection are used, among which are the impedance ground relay and the same type of power directional relay which is used for phase protection, except in the case of extremely long lines where, if the fault current is less than load current, other means of protecting the lines must be found.

It has also been the experience of this and other companies that the most satisfactory method of checking the connections of ground relays has been by actually placing grounds upon the lines in question, since there is less chance of error in this method than in any other. It is further felt that the increased cost of this method of testing is entirely justified from the standpoint of the better relay operation obtained, and from the standpoint of reduction in number of interruptions, which is very important.

Discussion

For discussion of this paper see page 864.

Directional Ground Relay Protection of High-Tension Isolated Neutral Systems

BY J. V. BREISKY[1], J. R. NORTH[2], and G. W. KING[3]

Associate, A. I. E. E. Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—*This paper discusses the problem of obtaining selective relay protection in case of accidental grounds on high-tension isolated neutral systems. A relay was developed whose overcurrent element operates on the residual charging current which exists when a ground occurs on such a system, and whose directional element is operated by residual charging current and residual voltage. Two schemes can be employed: One using high-tension potential transformers for energizing the voltage coil of the directional element; the other, which is more complicated but cheaper, making use of low-tension potential transformers.*

Tests were undertaken on the 140-kv. system of the Consumers Power Co. to determine the effectiveness of this relay system under conditions of arcing and solid grounds. These tests were successful and it was therefore decided to make general use of such relay equipment for the high-voltage isolated neutral system. The relay scheme was put into operation during March, 1926, and the operating records available adequately substantiate the test results.

* * * * *

INTRODUCTION

SELECTIVE protection in case of accidental grounds on systems either solidly grounded or grounded through a resistance is a problem which has been solved for some time in a satisfactory manner. The paper which is being presented at this same convention by Mr. B. M. Jones and Mr. G. B. Dodds gives an outline covering the different relay systems which are commonly in use today. It was only for ungrounded systems, however, as well as systems grounded through an extremely high resistance, that no satisfactory solution had been found. It is true that a residual voltage relay has been used to indicate the presence of a ground on an ungrounded system, see scheme in Fig.

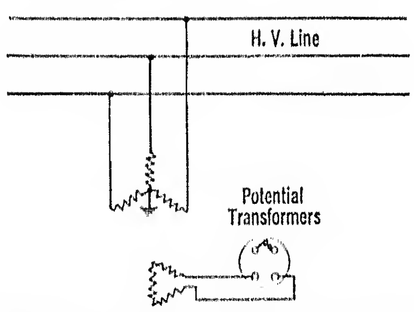

FIG. 1—RESIDUAL VOLTAGE RELAY FOR INDICATION OF ACCIDENTAL GROUNDS

1, but such a relay can be used for indication only, as it will operate no matter at which point of the system the ground occurs.

In this paper a relay protective scheme is described which offers a solution of this problem. It makes use of the residual charging current for timing and of the residual charging current and residual voltage for directional discrimination. It can be used successfully on ungrounded systems operating at high voltages and having lines of considerable length.

THEORY AND DESIGN

General Theory. As is well known, the charging current obtaining on a three-phase system under normal conditions is caused by the capacity between wires as well as from each wire to ground. Since the capacity currents are equal in all three phases, the current in the neutral of three current transformers connected to the three phases of the system is normally zero. If a ground occurs on one of the phases, the balance is disturbed, however. While the charging current due to the capacity between wires is still the same, assuming that the ground current is not large enough to influence the potential between conductors considerably, the capacity from each wire to ground has changed. One of the phases is at ground potential, resulting in no charging current to ground, and the other two are now 1.73 times normal line to neutral voltage above ground. Therefore, a residual charging current results. This is shown schematically in Fig. 2, Fig. 2A showing normal conditions and Fig. 2B showing vector relations in case of a ground on phase A; charging currents due to the capacity between wires are not shown, as they stay balanced and do not contribute to the residual current. The vectors for residual voltage are also shown in Fig. 2. Under normal conditions, the secondary delta of the star-delta potential transformer is closed, giving zero residual voltage. The star side of the potential transformer must be grounded. In case of a ground on one of the phases, *e. g.*, phase A close to the station, E_a becomes zero, while E_b and E_c increase 1.73 times and also change in phase position. It is seen that the secondary delta is not closed any more and a residual voltage equal to three times the normal secondary delta voltage appears.

Studying the phase relations between currents and voltages, it will be noted that the normal charging current to ground in each phase leads the voltage between that phase and ground by 90 deg. and that under ground fault condition, the residual charging current also leads the residual voltage by 90 deg.

Graphic Representation of Residual Charging Current. In order to gain a clear conception of the operation of

1. Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
2. Commonwealth Power Corp., Jackson, Mich.
3. Consumers Power Co., Jackson, Mich.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

this relay system, the distribution of the residual charging current over the line must be studied. An excellent equivalent method of arriving at the residual currents has been published,[4] the gist of which is given here. With a solid ground at a certain point of the system, the potential between the grounded conductor and the ground is reduced to zero at that point, the normal potential between line and ground being indicated by E_n, Fig. 3. Instead of studying this problem now as a three-phase unbalance, let us assume that all constants of the system remain unchanged and that a single-phase potential whose value is $-E_n$ is superimposed over the normal potential at the point of accidental ground. The sum of these two potentials, E_n and $-E_n$, is zero, corresponding to a solid ground. The only difference between the system under normal conditions and in case of an accidental ground is now caused by this superimposed potential $-E_n$. Due to the effect of this superimposed potential, a ground current I_g is established which flows into the ground and divides itself up through the three parallel branches of the capacity to ground, C, of the polyphase system. It flows through these back to the ground connection, on the grounded phase directly and on the two ungrounded phases through the windings of the transformers; see Fig. 3B. In the grounded conductor, the ground current due to $-E_n$ neutralizes the normal capacity current. The latter is not shown. In the ungrounded conductors, it adds to the normal capacity current.

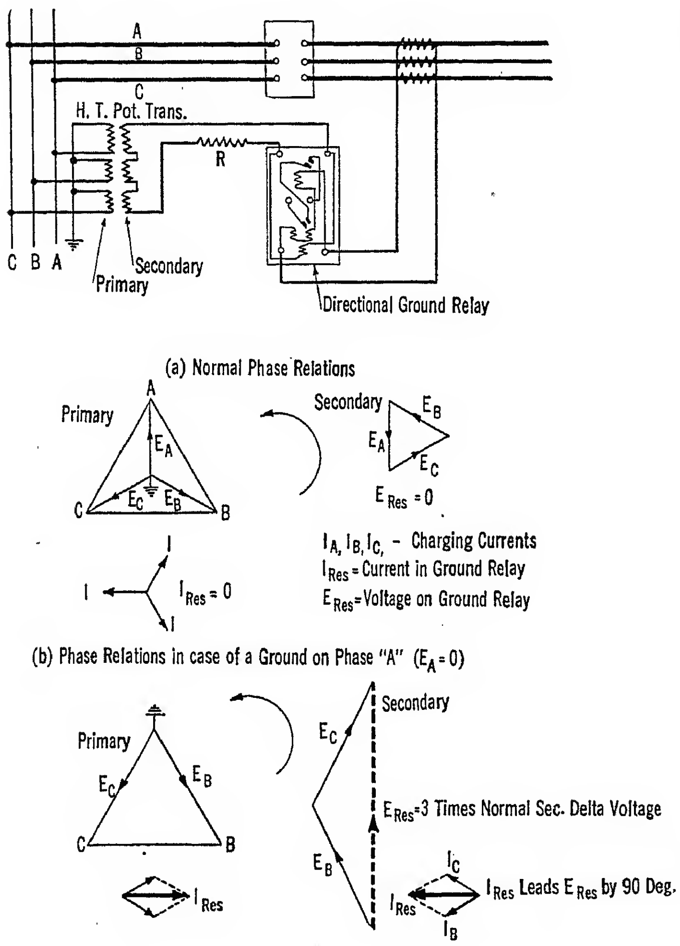

FIG. 2—VECTOR RELATIONS ON HIGH- AND LOW-VOLTAGE SIDE UNDER NORMAL CONDITIONS AND IN CASE OF ACCIDENTAL GROUND. RELAY SCHEME EMPLOYS HIGH-VOLTAGE POTENTIAL TRANSFORMERS.

The charging currents enter the system equally distributed over the entire length so that the current in all three conductors increases lineally from the far end. An interruption of the linear relation exists in the grounded conductor at the point of ground. To the right of the ground point, the current flows in the same direction as in the ungrounded conductors; to the left, that part of the ground current which is caused by the grounded line itself flows through its own circuit to the point of ground, increasing in the opposite direction. Also, the two currents of the ungrounded conductors combine and return over this conductor to the ground point.

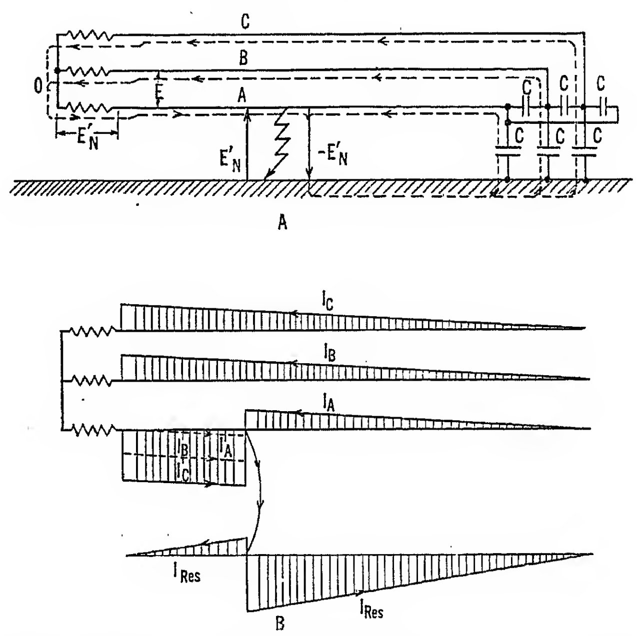

FIG. 3—GRAPHIC REPRESENTATION OF RESIDUAL CHARGING CURRENT

The distribution of the ground or residual current is obtained by adding the charging currents in each phase. This current is also shown in Fig. 3B. In the earth, one part of the current spreads out along the conductor path to the right and the other to the left. Both have a linear increase.

This current distribution, due to the accidental ground connection, superimposes itself over the normal current of the system, both the normal capacity and normal load currents, and produces a single-phase load and therefore dissymmetry in the potential and current of the system.

4. See R. Rüdenberg, "Electrisoke Schaltvorgänge", pp. 150-152, Julius Springer, Berlin, 1923.

The total residual charging current depends on the constants of the line and can be calculated rather accurately.

Calculation of Residual Charging Current. The capacity to ground is given by the formula:

$$C = \frac{0.03882}{\log_{10} \dfrac{2\,h}{r_0}} \ (\mu \text{ f. per mile})^5,$$

where

h = height above ground in inches,

r_0 = equivalent radius of line conductors in inches.

The value of r_0 for different circuits may be computed as follows:

One circuit on pole:

$$r_0 = \sqrt[3]{r\,d^2}$$

Two circuits on same pole:

$$r_0 = \sqrt[6]{r\,d^5}$$

r = average physical radius of conductor in inches,

d = effective spacing of conductors in inches.

Capacity per mile, in farads:

$$C = \frac{0.03882}{\log_{10} \dfrac{2\,h}{r_0}} \times 10^{-6}$$

Admittance per mile, in mhos:

$$Y = 2\,\pi\,f\,C$$

The residual charging current in amperes per mile, in case of ground on one phase:

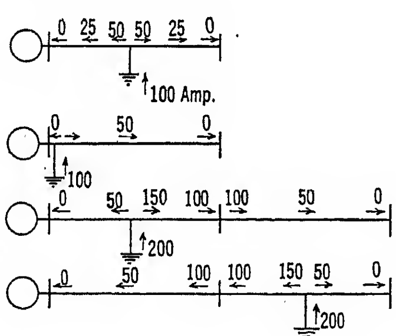

Fig. 4—Distribution of Residual Charge Current

$$I = E_n\,Y \ (E_n = \text{line to neutral voltage})$$

The series impedance, the impedance which the conductors offer to the flow of charging current, is negligible in comparison with the impedance to ground through capacity, and therefore has been neglected in the above calculations.

The residual charging current in a grounded polyphase system is three times as great as the normal capacity current to ground of each ungrounded conductor.

5. Refer to Standard Handbook for Elec. Engrs., 5th edition, p. 82.

Behavior of Residual Charging Current. Referring back to the distribution of the residual charging current as shown in Fig. 3B, bottom, let us now note certain important facts in regard to the behavior of this current under different conditions of system connections and grounds.

a. The residual charging current is a maximum at the point of fault, and is zero at the far ends of the line.

b. The total value of residual charging current is practically constant for a given length of line, voltage, etc., no matter at which point of the line the ground occurs, neglecting the series impedance. This is illustrated in Fig. 4.

c. The value of the residual charging current is

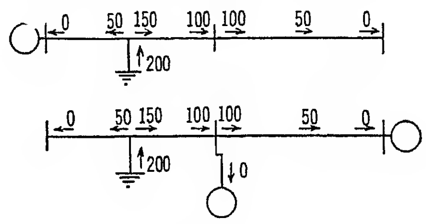

Fig. 5

Fig. 5—Distribution of Residual Charging Current

constant, regardless of the location of generating capacity, since no residual current can flow through ungrounded apparatus. The three line currents must add to zero in the apparatus; see Fig. 5.

d. In the case of single lines, the value of residual current at a given distance from the end of a line, and for a given direction of current flow, is constant no matter at which point of the system the ground fault occurs; see Fig. 4.

Relay Protection. In order to utilize properly the characteristics of the residual charging current, a relay is used which has both a current and a directional element; see Fig. 2. The directional element utilizes the residual current and residual voltage and closes its contacts only if power flows in a given direction. The current element is energized by the residual current and can be used either on the definite minimum or inverse part of the time curve, since the relay can be set to close contacts in a given time with a certain current flowing. As mentioned before, the current through the relay is constant for a ground at any point on the system, for a given system connection and given direction of power flow.

Fig. 6 shows a typical radial single line system. The time settings of the relays for given currents are indicated, as well as the tripping direction of the directional element. Grounds are assumed at several points to illustrate the operation of the relay system.

Since there is no residual current at the extreme end of the line, charging current ground relays cannot be made to operate at that point. However, a residual voltage relay, as shown in Fig. 1, can be used at the far

end of the line, set for a long time delay, so that it will not interfere with the time selectivity at other points.

Protection of Parallel Lines. The protection of parallel lines can be accomplished in two ways. The simplest solution is the use of differential current ground relays, operating on the unbalance of the residual currents in the parallel lines, with a ground on one of them. Another solution is the use of directional current relays as employed on single lines, except that here they must be used on the inverse portion of the time curve to obtain proper selectivity.

This problem is discussed in more detail in connection

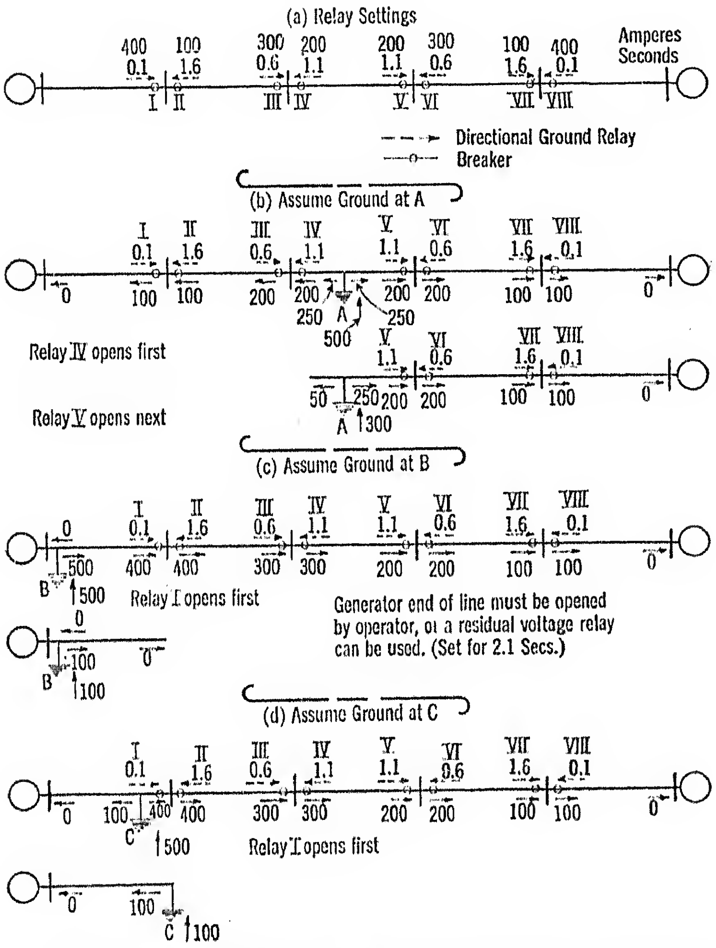

FIG. 6—APPLICATION OF DIRECTIONAL RELAY—OPERATING ON RESIDUAL CHARGING CURRENT—TO A RADIAL SINGLE LINE SYSTEM

with the relay system used by the Consumers Power Company.

Design of Relay. The design of this relay was a simple problem, after the behavior of the residual charging current and voltage had been studied. A standard low energy directional relay is used, except for the current phase-angle relations in the potential coil. As is evident from Fig. 2, the residual charge-current leads the residual voltage by 90 deg., neglecting a shift due to the series impedance of the line, which may shift the current 10 deg. to 15 deg.

The standard directional relay as used for short-circuit protection is designed to give maximum torque if the current in the current coil and the voltage in the voltage coil are in phase. This is achieved by lagging the current in the potential coil by almost 90 deg., since maximum torque in an induction element is obtained with the two fluxes, or two currents, 90 deg. out of phase.

Now, in the residual charging current relay, the current normally leads the residual voltage by almost 90 deg. Therefore, to obtain good torque conditions, the current in the potential coil is brought practically in phase with the potential, by adding a resistor R, Fig. 2, in series with the potential coil. The vector relations in the relay are shown in Fig. 7. It should be pointed out that the current and voltage in the relay are zero except in case of a ground, thus permitting the use of a sensitive device.

Scheme using Low-Tension Potential Transformers. The relay scheme discussed so far necessitates the use of high-tension potential transformers, since the unbalance of the neutral voltages on the high-tension side is not transmitted to the low-tension side through a power transformer bank if the high-tension side of the bank is ungrounded.

Naturally, high-tension potential transformers in-

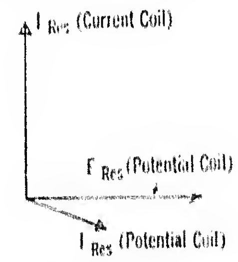

FIG. 7—VECTOR RELATION OF CURRENT AND POTENTIAL OF RELAY COILS

volve a great expense on high-voltage systems. For this reason, another relay scheme was worked out which can be used in connection with low-tension potential transformers.[6] It necessitates complication of connections and great care in checking polarities, but it will bring about material savings in cost.

The connections are shown schematically in Fig. 8. Three directional relays are required. All three use the residual charging current but the potential element of each is connected to a different delta voltage. The wiring sketch shows the method of connections. When any two of the main relays close, either of the two auxiliary relays will pick up. If only one main relay closes contacts, neither of the auxiliary relays operates. The auxiliary relays are so connected that either will trip the breaker.

Vector diagram I shows the normal vector relations of a three-phase system. Vector II shows conditions with line A grounded, I_{AR} being the residual charging current. Diagram III is intended to show the currents

6. This scheme was developed in cooperation with Mr. H. A. Travers.

in the relay current coils with grounds on the different phases. I_{AR}, I_{BR}, and I_{CR} are the residual charging currents for conditions of lines A, B, and C respectively grounded. Of course only one of these currents exists at a time. The currents in the potential coils are made to lag 30 deg. behind their respective voltages.

If we now consider the condition of a ground on line A, we will have the current I_{AR} flowing in the current coil of each relay. If the relays are adjusted so that with the current in the potential coil leading the charging current between 0 deg. and 180 deg., the contacts will close, while if the current in the potential coil is lagging 0 to 180 deg., the contacts will be held open. It is evident from an inspection of the diagram that relays carrying potential coil currents I_{BC} and I_{CA} will close their contacts, while the relay carrying potential coil current I_{AB} will remain open. Since two

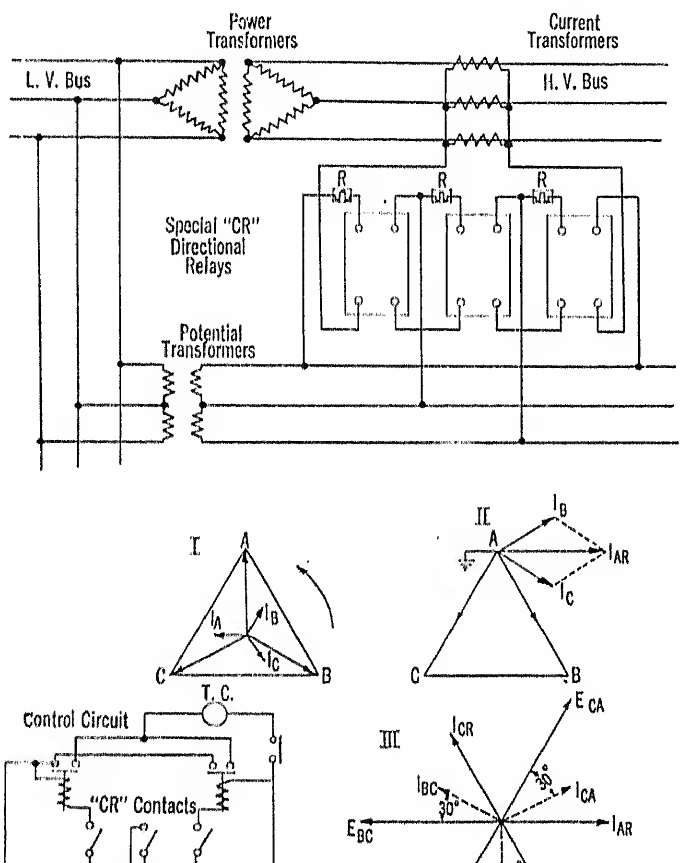

FIG. 8—RELAY SCHEME EMPLOYING LOW-TENSION POTENTIAL TRANSFORMERS

of the relay contacts close, the auxiliary relay will close and the breaker will be tripped. If, without changing anything else, the current I_{AR} flows in the opposite direction, it is clear that the reverse action would occur; *i. e.*, two relays would remain open and one would close, thus not operating the auxiliary relays and not tripping the breaker. With a ground on phase B or C, similar action takes place. Taking advantage of this fact, directional protection can be secured.

As mentioned before, the currents in the potential coils are made to lag 30 deg. behind their respective voltages. This scheme will function correctly if the position of I_{AR}, I_{BR}, and I_{CR} does not shift more than 30 deg. in the lead or lag direction, from the position shown in diagram III, which assumes that the residual charging currents lead their respective neutral voltages by 90 deg. In practical applications, it will be found that the residual charging current leads by somewhat

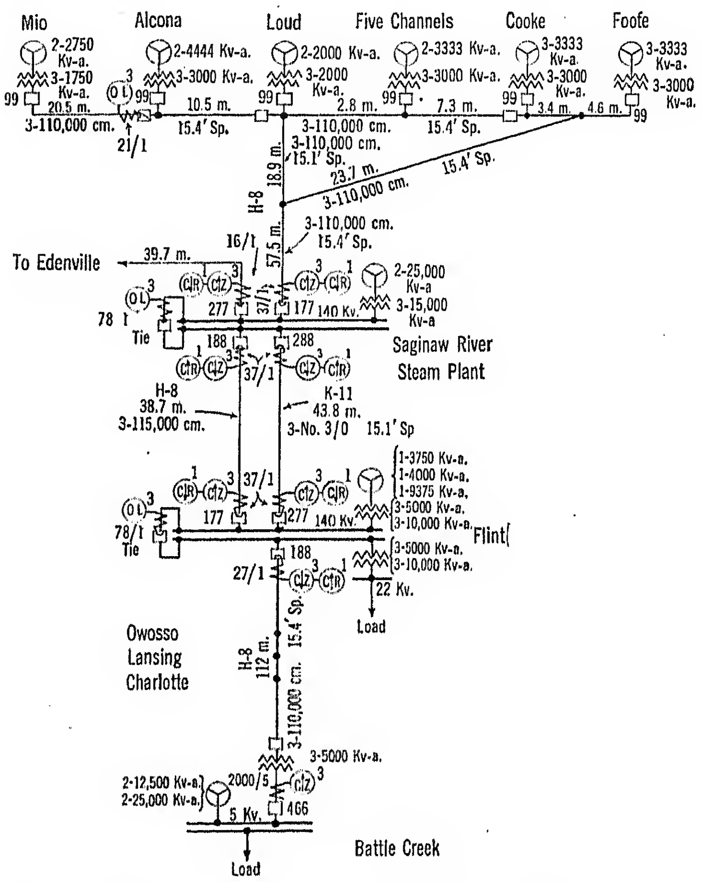

FIG. 9—SYSTEM CONNECTIONS OF 140-KV., 60-CYCLE, H-8 SYSTEM

less than 90 deg., on account of the series impedance of the line, making it more advantageous to somewhat increase the lag of the current in the potential coils, by changing the series resistors.

APPLICATION

System Connections. The Consumers Power Company has a 140-kv., 60-cycle isolated neutral transmission system having a total connected length of approximately 380 mi. and extending from hydroelectric generating plants in the northern part of the state down along the eastern side through Saginaw, Flint, and across to Battle Creek. This is known as the "H-8" system and is shown in a simplified manner in Fig. 9. Power is supplied from hydroelectric generating stations on the Ausable River and the steam generating stations at Saginaw, Flint, and Battle Creek. Important

loads are served from this transmission system at Saginaw, Edenville, Flint, Owosso, Lansing, Charlotte, and the Battle Creek stations.

Protective Requirements. The usual transmission-line faults may be classified as phase-to-phase short circuits or line-to-ground failures and any system of relay protection installed should effectively isolate the particular section of transmission line in trouble from the rest of the system with the least possible disturbance and under all operating conditions. An additional requirement of this particular system is that the relays

*Effective line length is the length of the connected line on opposite side of ground relays from ground fault. (Effective in producing residual charging current through relay.)

must allow large amounts of power to be fed in either direction under normal conditions, since generating capacities and large loads are located at various points.

After studying the problem, type $C\,Z$ directional impedance relays were recommended to take care of phase-to-phase short circuits since they would satisfactorily fulfill the requirements. Directional overcurrent relays could not be used as they would not allow large blocks of power to be fed in either direction and at the same time take care of minimum short-circuit conditions. Also, they would not give positive selective action for faults occurring on the Saginaw-Flint tie lines. Current balance relays could not be used on the tie lines because of the possibility of not operating them in parallel.

Protection in case of line-to-ground faults could not be obtained with the ordinary schemes of ground relaying since this is an isolated neutral system and the unbalance of the charging current to ground is the only definite indication of ground fault conditions; therefore the relaying scheme described in the first part of this paper was developed to take care of such fault conditions.

Field Tests. In connection with the application of this ground relaying scheme, it was decided that a field test should be made to check the theoretical calculations of the amount and distribution of residual charg-

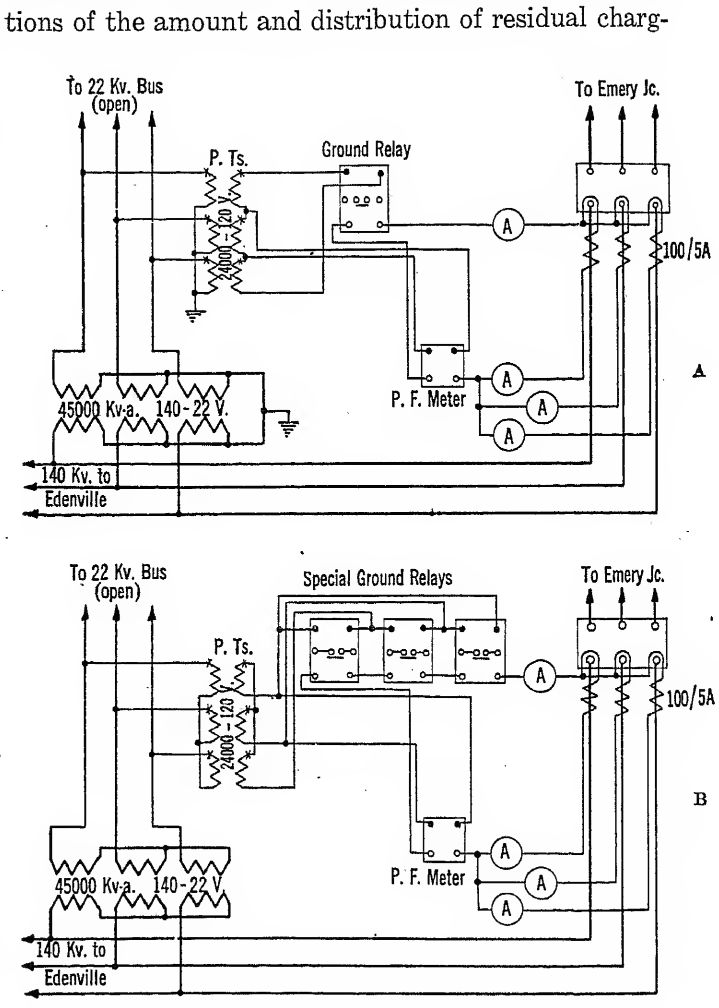

FIG. 11—RELAY SCHEMES USED FOR GROUND TESTS

A. High-voltage potential transformer scheme
B. Low-voltage potential transformer scheme

ing current under ground fault conditions and also to observe the actual operation of the special directional ground relays which had been developed. Fig. 10 shows the system connections, generating capacity, test connections, and fault conditions during the tests. Power was supplied by hydroelectric generating stations on the Ausable River feeding through the 140-kv. lines to the Saginaw River Steam Plant and on to Edenville. The connected length of line and the generating capacity used during the tests are indicated.

Both solid and arcing ground tests were made, the latter conditions being obtained by connecting a line wire to approximately 300 ft. of wire lying on the ground.

Two different schemes of ground protection had been developed, one using high-tension potential transformers and the other using low-tension potential transformers. Both schemes were tested out at this time and the detailed test connections used are shown in Fig. 11, A and B. The regular high-tension potential transformers were not available for these tests and therefore a large bank of Y-Y-connected, 140/22-kv. power transformers was used to step the voltage down from 140 kv. to 22 kv. The neutrals of this Y-Y transformer bank were grounded when testing scheme No. 1, but not when testing scheme No. 2. In each case, 24,000/120-volt potential transformers were used to supply potential for the relays and they were connected Y-Y for testing scheme No. 1 and Y-delta for scheme No. 2.

Four special type $C\ R$ directional ground relays were provided, one for scheme No. 1 and three for scheme No. 2, together with various indicating meters at the Saginaw River Station. A standard 100/5-ampere, 15-kv. instrument current transformer was connected in the ground lead at the point of fault and a high speed graphic ammeter, having a roll speed of approximately nine in. per min., was used to give an indication of the actual amount of ground fault current obtained. The various tests were made as follows:

Test no.	Relay scheme	Ground: Location	Ground: Nature
1	Low tension (No. 2)	Edenville	Solid
2	Low tension (No. 2)	Edenville	Arcing
3	High tension (No. 1)	Edenville	Arcing
4	High tension (No. 1)	Saginaw River	Solid
5	Low tension (No. 2)	Saginaw River	Solid
6	Low tension (No. 2)	Saginaw River	Arcing

The results of the above tests were satisfactory and a summary of them is given in Table I.

Some line trouble in the nature of high-resistance intermittent grounds was experienced before and during the tests, which trouble was later found to be due to the line arcing into trees north of Saginaw. This somewhat affected the results, especially the accurate observation of current and voltage readings. It should be noted here that, judging from subsequent data on relay operations, during fault conditions, the actual ground currents obtained must have been within 10 to 20 per cent of the calculated values since the actual tripping time of the relays was very close to the calculated time. The test demonstrated that scheme No. 1, using high-tension potential transformers, will work satisfactorily with either a solid or with an arcing ground.

Because of the line trouble experienced, the test of the scheme using low-tension potential did not give conclusive evidence of satisfactory operation, although correct indications were observed. Therefore a further test of this scheme was made extending over a period of several weeks, this being in the nature of an operating test with the relays connected so that their operation under actual system conditions would be recorded.

Fig. 12 shows the connections used in making this operating test and it will be noted that the current elements of the three special $C\ R$ relays were connected in series with a graphic ammeter in the neutral circuit of the bushing current transformers on one of the 140-kv. line breakers. The relays received their potential from delta-delta-connected potential transformers located on the 22-kv. side of 140/22-kv., delta-delta-connected power transformers. Graphic voltmeters and indicating lamps were connected in series with the relay contacts across a 125-volt storage battery so that in case any of the relays operated, a definite indication and record was obtained. These relays were intended

to operate as follows: When a line-to-ground fault occurred on the 140-kv. system, either one relay alone should operate, or two should operate and the other one not operate, depending on which side of the 140-kv. oil circuit breaker the fault occurred.

This test installation gave good results; for example, a ground fault occurred on the Y-phase of the 140-kv. line, approximately 80 mi. out on the Battle Creek line, and during this case of trouble, No. 2 indicating lamp flashed for approximately 15 sec. and No. 3 indicating lamp flashed for approximately 60 sec. This relay operation was checked and the vector diagrams shown in Fig. 12 indicate that the operation was correct.

Bushing Type Current Transformer Tests. At the time the application of these ground relays was being

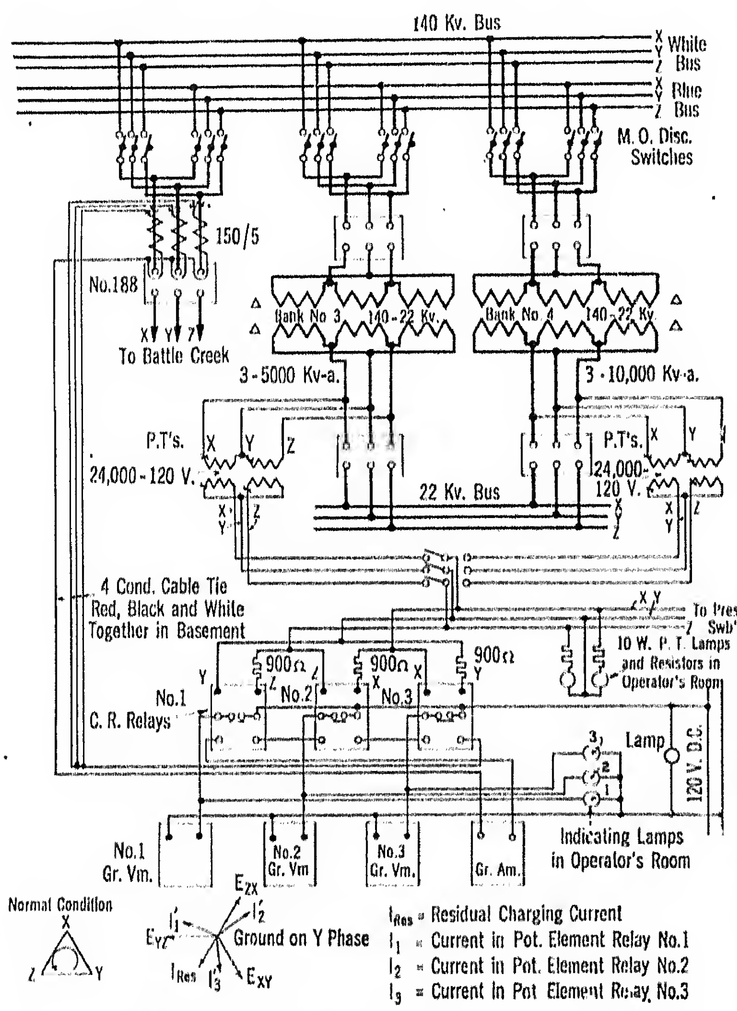

FIG. 12—CONNECTIONS USED FOR GROUND RELAY OPERATION TESTS AT FLINT, GARFIELD AVENUE SUBSTATION (LOW-TENSION POTENTIAL TRANSFORMER SCHEME)

studied, there was little information available regarding the actual ratio and phase-angle characteristics of bushing type current transformers, especially under conditions of low or unbalanced primary currents and high secondary burdens. The amount of residual charging current available is small even under the best conditions and its phase relation is such that the phase-angle errors of the current transformers should be known, particularly for the low-tension relay scheme. The directional ground relays impose a considerable burden on the current transformers, it being in the nature of eight ohms or one volt-ampere per relay at the minimum tripping current. For these reasons, special ratio and phase-angle tests were made on several bushing type current transformers under conditions of primary cur-

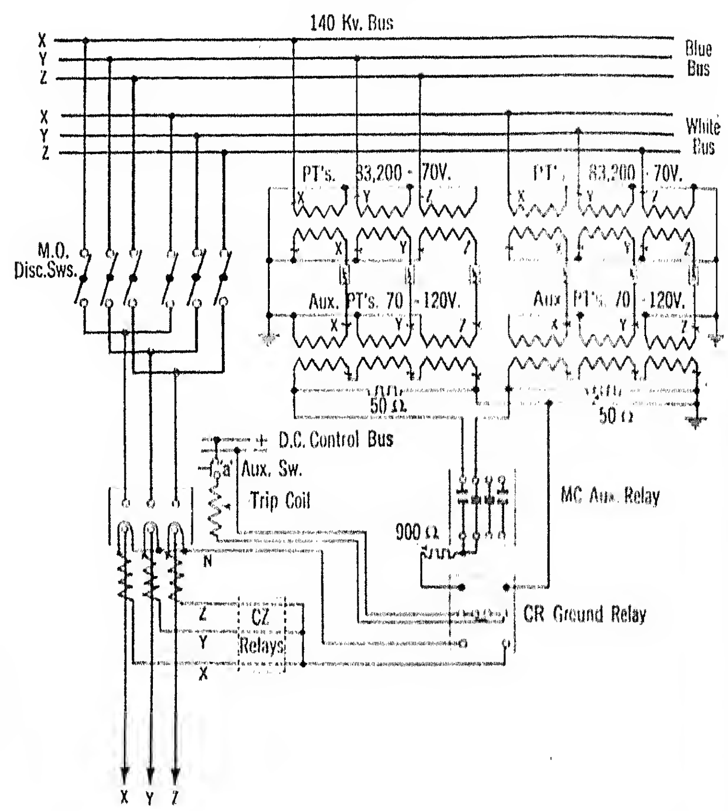

FIG. 13—DIRECTIONAL GROUND RELAY PROTECTION USING HIGH-TENSION POTENTIAL TRANSFORMERS

rents and secondary burdens approximating those which were expected in service with the ground relays. The results of these and subsequent tests may be summarized as follows:

1. The true effective ratio of bushing current transformers of a given design depends on the primary current and the secondary burden. Under balanced conditions and with a constant secondary burden, the true ratio improves as the primary current is increased up to the saturation point of the core and then increases. At low values of primary current, such as the residual charging current, practically all the current is utilized for excitation and very small currents are obtained in the secondary circuit.

2. Under unbalanced conditions, such as line-to-ground faults, and with a heavy neutral burden, the current in the neutral circuit of such transformers is considerably less than the ordinary ratio characteristics would indicate. This is due to the other two current tranformers and their secondary circuits forming a shunt across the transformer in the grounded phase and part of the fault current flowing through them rather

than through the neutral circuit, thus giving a higher effective ratio for the neutral circuit.

3. The phase-angle error of bushing current transformers is quite large, varying in some cases from one-deg. lag to 15-deg. lead over a range of 50 to 200 per cent of rated primary current and at moderate burdens.

In view of their variable ratio characteristics, all bushing current transformers are tested after installation under conditions approximating actual operating conditions. In the case of transformers used with ground relays, they are now tested under both balanced and unbalanced conditions and the relay settings are based on the true ratio characteristics. Bushing current transformers cannot be used with the type of ground relays as applied here unless the minimum residual charging current is 80 amperes or more. In some installations it has been found desirable to use two transformers per phase, connected in series, where the available residual current is low. Such an arrangement materially improves the true ratio at low values of primary current.

Installations. One type *CR* directional ground current relay is used for ground protection on each of the 140-kv. lines at the Saginaw River Steam Plant and connected as shown in Fig. 13. The oil circuit breakers are equipped with three bushing type current transformers and the current coil of the ground relay is connected in the neutral circuit of the bushing current transformers. Two banks of high-tension potential

TABLE II

TOTAL RESIDUAL CHARGING CURRENT

Transmission line section	Length	I
Ausable to Saginaw	149.2	97
Edenville to Saginaw	39.7	26

Saginaw to Flint (K-11)	41 (Av.)	27
Flint to Battle Creek	111	72

transformers rated 83200/69.2 volts and connected *Y-Y* grounded are used, together with 70/120-volt auxiliary potential transformers connected *Y*-delta to furnish the potential for the ground relays. The auxiliary potential transformers are necessary because the high-tension potential transformers must be connected *Y-Y* and used for other relaying and synchronizing purposes. The potential coils of the ground relays are connected inside the delta circuit of the auxiliary potential transformers. One set of potential transformers is connected to each 140-kv. bus and auxiliary relays are provided to automatically transfer the potential circuits of the relays from one set to the other in case either one is de-energized.

A similar installation of directional ground relays and potential transformers is provided for the various 140-kv. lines at the Flint-Garfield Avenue Substation. The directional ground relays cannot be used at the end of a single line and therefore they are not installed at the present time at Edenville or Battle Creek. Also, no residual voltage relay is used at these stations since no high-tension potential transformers are available.

Ground Current Calculations. The amount and division of ground current flowing under various conditions of line-to-ground faults was calculated in order to determine the proper relay settings. These calculations were based on the line capacity and residual charging current formulas previously given. All the necessary circuit data are given in Fig. 9, except for the average height above ground, which is 50 ft. Therefore, for the

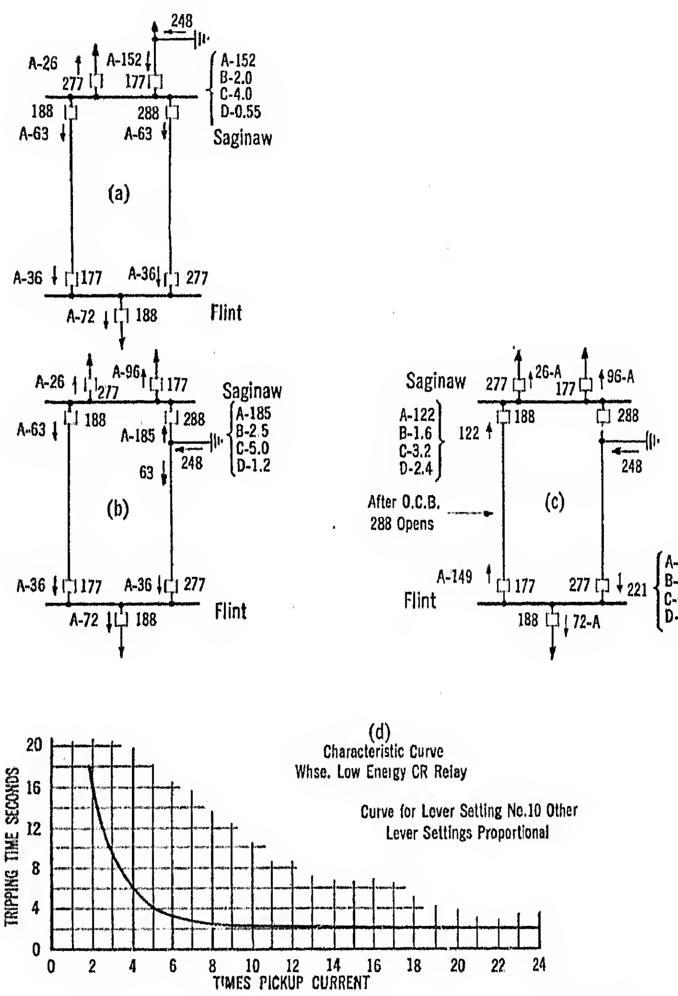

FIG. 14—DIVISION OF RESIDUAL CHARGING CURRENT UNDERGROUND FAULT CONDITIONS

lines on this particular system, h = 600 and r_0 (average) = 18.2. Substituting these values in the formulas:

$$\text{Capacity } (C) = \frac{0.03882}{\log_{10} \dfrac{2\,h}{r_0}} \times 10^{-6} = 0.0214 \times 10^{-6}$$

farads per mi.

Admittance (Y) = $2 f C$ = 8.06×10^{-6} mhos per mi.

Residual charging current (I) = $E_n\, Y$ = 0.65 amperes per mi.

The total residual charging currents for the various sections of transmission lines are given in Table II.

As previously mentioned, the division of residual charging current depends on the transmission line lengths and connections. The calculated division of residual charging current and the relay operation for several assumed conditions of line-to-ground faults are given in Fig. 16, A, B, and C. In Fig. 14A, a line-to-ground fault is assumed on the H-8 north line at Saginaw and the total residual charging current at the fault is 248 amperes; of this, 152 amperes pass through breaker No. 177 and the rest flow in the opposite direction. The current through breaker No. 177 further subdivides as indicated. The 152 primary amperes give 2.0 secondary amperes and with the relays set on current tap 0.5 and lever No. 1, they will operate in 0.6 sec. as shown by their time-current characteristic curve, Fig. 14D. Figs. 14B and 16C show the division of residual currents in case of a line-to-ground fault on one of the Saginaw-Flint tie lines at Saginaw. Under such conditions and with the tie line relays set on current tap 0.5 and lever No. 3, the relays on breaker No. 288 at Saginaw will operate in 1.2 sec. and those on breaker No. 277 at Flint will operate in 2.15 sec., total time from occurrence of fault. The current and time settings used on all the relays are given in Table III.

The values of residual ground current obtainable are small and the relay current settings were therefore made as low as possible. The relays on each end of the Saginaw-Flint tie lines were set to operate on the inverse part of the time-current curve so as to operate selectively under all conditions. The time settings selected were such as will give a rather long time delay in order to allow minor flashovers to clear themselves before the relays operate. This helps to prevent disconnecting the lines unless serious trouble develops.

Testing Directional Connections. Each directional ground relay must be connected so that it will operate in the proper direction when a ground fault occurs on its particular line. The residual charging current has a 90-deg. phase relation with the residual voltage and it would be desirable to be able to test these relays by actually putting a ground on the line but this cannot be conveniently done on this system and therefore the proper conditions have to be approximated by an artificial similation of grounded conditions using normal voltage and load currents.

De-energizing one phase of the auxiliary potential transformers gives a potential across the ground relay terminals which will have the same relative phase relation as the residual potential across the relay terminals when the X-phase of the line is grounded. The relay should thus operate properly with this potential and with a current leading it by 90 deg. If actual load currents are used, the direction of power flow must be ascertained in order to determine whether the directional contacts of the relay should open or close under the test conditions.

The actual procedure used in testing the directional setting of these ground relays is as follows: (refer to Fig. 13).

The fuse in the secondary circuit of the X-phase potential transformer is removed and the primary of the X-phase auxiliary potential transformer short-circuited.

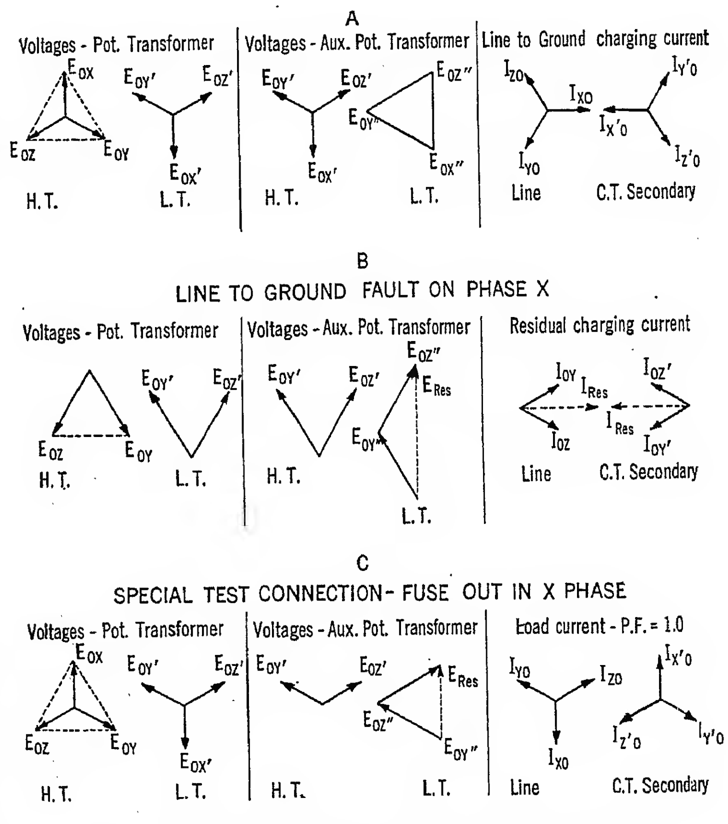

FIG. 15—VECTOR DIAGRAMS, METHOD OF TESTING DIRECTIONAL SETTINGS

Fig. 15A shows the vector diagrams of voltage and line-to-ground charging current under normal balanced conditions. Fig. 15B shows the vector relations between voltage and residual charging current with the X-phase grounded, and Fig. 15C shows the vector relations between the voltage and load currents with the fuse in the X-phase of potential transformers removed and with a load of unity power factor. It will be noted that the potential across the relay terminals with the fuse removed has the same relative polarity and is of $\frac{1}{3}$ the value of the potential with the X-phase grounded.

The phase relation of the normal voltage between X and neutral, low-tension side of high-tension potential transformers, and the load currents in phases X, Y, and Z are next determined by means of a phasemeter. The potential across the relay terminals is then compared with the normal voltage between X and neutral by checking with any one of the load currents previously used. These tests definitely fix the phase relation between the load currents, the normal potential between X and neutral and the test potential on the relay.

The actual direction of power flow in the line is next determined and the relays set to operate as follows:

a. With power flowing from the line into the bus, the relay should close its contacts with the current leading the voltage by 90 deg.

b. With power flowing from the bus out to the line, the relay should open its contacts with the current leading the voltage by 90 deg.

Operation and Results

Potential Transformer Secondary Fuses. In checking some relay operations soon after they were placed in service, it was discovered that trouble was being experienced due to the blowing of the fuses in the potential transformer secondary circuits. No particular attention was paid to this feature at the time of installation, it being felt that it could be treated the same as any other potential transformer installation and secondary fuses of three-ampere capacity were used. The blowing of these secondary fuses constituted a very serious condition for several reasons. These potential transformers are used for relaying, metering, and synchronizing; thus, with these fuses blown, the relays were helpless; there was no indication of potential and it was impossible to synchronize the lines.

The three-ampere fuses were replaced by ten-ampere ones and tests arranged to determine the cause of the high current flow. One feature of the situation was that the abnormal current did not depend upon line trouble in all cases but occurred very often during switching operations. The tests were made with one set of potential transformers connected to a long section of line and entirely isolated from the rest of the system. Various switching operations were performed with this section of line and the voltage and currents of the potential transformer circuits noted. The results of these tests were very interesting. It was discovered that the heavy current flowed in the transformer circuits when de-energizing the line rather than when energizing it, the current flow being of very short duration, less than one sec. Also, there was no noticeable voltage surge. The current observed at this time was of the order of 20 amperes but the duration was so short that the 10-ampere fuses were not blown. It was felt, therefore, that ten-ampere fuses were of ample capacity. These fuses, however, were later blown during line trouble and a graphic ammeter left in the circuit indicated a current of nearly 40 amperes on one occasion. Fuses of higher rating were installed, finally reaching 30 amperes, but still some trouble was experienced. In the meantime, the problem had been investigated more thoroughly and it was suggested to install a 50-ohm resistor in parallel with the ground relay potential coil. This suggestion was based on the following consideration. The potential transformers in question are the only pieces of apparatus on the system whose neutrals are grounded. When the transmission line is de-energized, the static charge on the line tries to dissipate itself through the primary windings of these transformers going to ground. In so doing, a high-frequency current of varying value is produced for a short time in the secondary circuit. It was felt that increasing the resistance of the circuit would cause the amplitude of the oscillations to decrease faster and, therefore, dampen out the disturbance more rapidly.

These resistors were installed the latter part of 1926 and since that time several cases of serious line trouble have occurred, as well as the usual switching operations, but no fuses have been blown.

Relay Operation. Approximately 75 per cent of the operations of these ground relays during 1926 have been found to be definitely correct. The remaining 25 per cent of the operations were questionable, as no indication of trouble was found. In connection with the questionable cases of operation, it should be understood that with the isolated neutral system, a great many cases of insulator flashovers have occurred and cleared themselves before any serious system disturbance developed. With the trouble which was experienced with potential transformer fuses blowing, there was always a question as to whether these fuses did not blow before the relays had a chance to operate in case of line trouble. Also, while these flashovers constitute a ground fault, the relays may operate before the damage to insulators or conductors is of sufficient magnitude to be noticeable on casual inspection.

Since the resistors were installed to prevent the fuses in the potential transformer secondary circuits from blowing, there has been no questionable operation. Several definite cases of ground faults have been isolated by these relays, and we feel confident that they will continue to operate in this satisfactory manner.

A point to be particularly mentioned in connection with these relays is the necessity of keeping the system connected at all times in order to obtain as much residual charging current as possible. Formerly, during times of storm, the system was split up in order to isolate any possible cases of trouble. With this method of relaying, however, it is essential to keep the system all connected together, and this is favorable to the present load conditions, as it is frequently impossible to split the system due to need for all of the generating equipment on the line.

Future Installations. Due to the very favorable operation of the relays which are installed at the Saginaw River Steam Plant and Garfield Avenue Substation, it is planned to increase the number of installations on the system. At large substations where it is planned to use high-tension potential transformers, the present relay scheme will be used. At the smaller stations having no high-tension potential transformer, the relay scheme utilizing the low-tension potential transformers will be used. With this second scheme, it is much more difficult to obtain the correct directional setting, but after the relays are installed and adjusted, they should work satisfactorily. Within the next year, these ground relays will probably be installed on the 140-kv. lines at our Owosso, Charlotte, and Blackstone substations.

Discussion

GROUND-RELAY PROTECTION FOR TRANSMISSION SYSTEMS

(Jones and Dodds)

DIRECTIONAL GROUND-RELAY PROTECTION

(Breisky, King, and North)

Detroit, Mich. June 21, 1927

H. P. Sleeper: I was not aware that we had progressed to the extent indicated by Mr. Breisky's paper, where we can actually place ground protection on a system where there is no ground current.

However, the method described by Mr. Jones in his paper is one which I believe indicates a distinct advance in the art. Perhaps five or six years ago it was a hard proposition to sell to operating engineers the idea of ground protection. At that time short-circuit protection was pretty much standardized, and they saw no necessity for complicating the situation.

However, today that is not the case, and I believe that ground protection is fully justified for two reasons in particular. In the first place, ground-relay protection will tend to minimize the damage at the point of fault. On the system with which I am identified, that of the Public Service Electric and Gas Company of New Jersey, we have several hundred installations of the type of ground-relay protection described by Mr. Jones. We are operating a 26-kv. system with 75 ohms in the neutral. This limits the current to ground to 200 amperes, high voltage. We find that its operation is extremely successful.

To illustrate the limiting of the damage at the point of fault, an example is a case which occurred recently when a ground was found at the joint of a 26-kv. cable. The line tripped out at both ends, and finally, by tests, the fault was located in the joint. The joint presented no external appearance of any abnormal condition within. The sheath was not enlarged nor blown apart, and there was no hole through it. The joint was opened, and there was a little hole through the compound, possibly as large as the end of one's little finger, showing where the current had gone to the sheath without burning through. On the conductor there was an extremely small amount of burning; so little that the joint was very easily re-made and re-insulated without the necessity of any additional line conductor being added.

The second effect, which really is an indirect one of the first result, is that of reducing the distress on the system. Prior to the installation of the 75-ohm resistor, we used the solid neutral on this system. A wire falling to the ground would give a severe voltage disturbance to the system, a 10 or 20 per cent dip being not uncommon during the trouble.

Now, a successful operation of the ground relays gives from 2 to 4 per cent voltage dip at the ends of the line which is not discernible on lights. I believe that this is very essential to the satisfaction of customers.

Another point that I should like to mention in connection with ground protection, is what I believe to be the necessity of making research faults on the system. I have made quite a few of such high-voltage grounds on the lines while investigating the efficiency of ground-relay protection, and in most cases to say the least I have found that the executives of the company were not heartily enthusiastic about the idea of making these faults. I believe that a certain amount of such testing is necessary as a research proposition.

That brings me to the third point which I should like to mention; namely, the methods of testing ground relays, to be certain they are properly connected and will operate correctly.

Mr. Jones has described the use of a phantom load, the use of the line load, and the actually making of faults on the high-voltage system, to check the ground relays. I have never been able to find a successful system of using phantom loads to do this. However, I find that the use of line load and line voltage can be used very successfully to check these relays.

We have devised a method of short-circuiting one current transformer while the line is carrying the load, and of opening one high-voltage disconnect switch without in any way disturbing the connections to the high-voltage system. With this method it is possible to obtain a set of phasing results on directional ground relays, which, to date, has given us no incorrect operations. I do not believe that the actual grounding of the high-voltage system is necessary.

I should like to say a word regarding Mr. Breisky's paper on the ground protection of isolated-neutral systems. As I understand the situation, the relay which has been developed to do this job is essentially the same relay that Mr. Jones has described wherein the system is actually grounded, the difference being that the relay on the isolated-neutral system uses charging current to operate it, and hence, different voltage relations result on the relay protection.

I should like to ask Mr. Breisky if it is not possible to use the same relay for both applications, thereby greatly simplifying a problem which is a difficult one for us right now. We have a system which has a neutral resistor at one station. If for any reason that one resistor must be removed from service, it becomes necessary or desirable to ground the system at some other point.

We have one system which has no duplicate resistor; therefore, the problem arose, shall we dead-ground the system or leave it ungrounded during the time the resistor is out? We tried dead-grounding the system but it was an unsatisfactory experience, for we found our ground-relay system worked backwards. I am referring to the ground relays which were tested to operate correctly with the 75-ohm resistor in the neutral. Hence our running orders are to leave the resistors isolated while the resistor is out. This we do not consider satisfactory. It occurs to me that possibly some method of external use of resistors and reactors would make it possible to use the same relay under all these conditions.

H. M. Trueblood: I have been interested in the two papers on ground relaying from a standpoint of which I think no mention has been made by the authors of either paper: I refer to the question of the control of inductive disturbances in exposed communication circuits at times of faults to ground in power systems. This in my judgment is one of the most important questions that we have in the field of inductive coordination.

Without desiring to enter upon any discussion of the relative merits and disadvantages of the various means that have been used or proposed for establishing and maintaining a relationship between a power system and the ground, I should like merely to say that it is an interesting thing that in the paper by Mr. Jones and Mr. Dodds, a reason is given for which a certain amount of resistance in the neutral ground connection is beneficial from the power operating standpoint. In the subsequent discussion of

that paper, we have heard statements to the effect that from the standpoint of power operation, such resistance is advantageous for two other reasons, limitation of damage at the point of fault and lowering of stresses on equipment.

We can take it for granted, I think, that so far as inductive coordination is concerned, the limitation of ground-fault current is desirable, and it is very agreeable and satisfactory to note that good reasons also exist for which such limitation is desirable from the standpoint of power system operation.

It would be interesting to know whether data exist, and if so, what they show regarding the optimum value of resistance from the standpoint of ground-relay operation. It would seem from the paper by Mr. Jones and Mr. Dodds that beginning with zero neutral resistance, a rapid increase in the wattage available for relay operation will at first be realized as the neutral resistance is increased, and that as further increases are made in resistance, the benefit will accrue less rapidly. This has been pointed out to me by Mr. A. E. Bowen, who has also noted that if the resistance is increased beyond a certain value, the wattage for relaying would probably decrease. It seems probable that there will generally be a considerable range of magnitude of neutral resistance over which the watts available for relay operation would be favorable, and not greatly dependent upon the magnitude of the resistance.

E. E. George: Our operating experiences on the Tennessee Electric Power Company system confirm a good many of the recommendations suggested by the Duquesne Light Engineers, but there are several points of difference,—some of which are undoubtedly due to different operating conditions.

Our system operates with solidly grounded neutrals at all generating stations, all substations which can supply power outward, and at a few receiving stations. The size of grounding transformers on the 120,000-volt system ranges from 7500 kv-a. to 50,000 kv-a. and from 200 kv-a. to 25,000 kv-a. on the 44,000-volt system.

We are certain that directional ground relays are absolutely necessary on our high-voltage transmission system, more especially since our parallel balanced lines are very few, and since trunk tie lines with other companies without isolating transformers are becoming more common.

However, our scheme of directional ground relaying is different from the scheme outlined this morning, and is, we think, simpler, and more reliable, at least for systems which have transformers suitable for grounded-neutral operation at practically all switching points. We are using directional ground relays operated by two currents instead of by a current and potential. One current element of the relay is supplied from the neutral or residual of the bushing current transformers in the line to be protected, and the other element is supplied from a current transformer in the neutral ground lead of the grounding bank. We formerly used relays which had separate over-current and directional elements with the directional disk operated by the two currents and the overload disk operated by one current. We are now using relays which have the over-current and directional elements combined in one disk.

Very probably all reverse power or directional ground relays on our system installed hereafter will have only one common disk, as we have found that relays with separate over-current and directional elements are likely to trip incorrectly due to surges which will close the instantaneous directional element regardless of fault location after the overload element has closed.

We have no objection to the system of protection outlined by Mr. Jones and Mr. Dodds and expect to use it at any point where we are unable to secure grounding transformers, since the installation of star-delta high-voltage transformers will undoubtedly be cheaper than buying a grounding bank in most cases.

We have had very poor success with ground relays interlocked with reverse power relays. We have only one such installation and it will be removed this year. We have had some sad experiences with this scheme on tie lines where there is a possibility of surging of power or reactive kv-a. during trouble. We have had reverse power relays on both sides of a large load center set to trip outward, drop the load during trouble that should have operated neither relay. We have also had a large number of cases where the power load was heavier than the ground current and the reverse power relays could not operate. Even with heavy grounding transformers we find that ground currents are often less than load currents and ground protection independent of load protection is absolutely essential.

The application of reverse power relays on large transmission systems is apparently very limited. We find that the reversal of power is an infrequent indication of trouble and often occurs during abnormal operating conditions, and we have eliminated all reverse power relays on this system, except at two stations.

We have had very satisfactory operation with balanced ground relays after we learned to interlock them through "A" switches on the breakers so that the second line could not trip immediately after the first line, except by back-up over-current ground relay.

We are absolutely in accord with the Duquesne Light Company on the necessity of placing grounds on the system to test out important relay installations. We have not standardized the equipment or procedure of this as we have only made five such tests to date, but on four cases we have solidly grounded the line with reduced generation on the system and read the ground current at a station distant from the point of grounding. On a long line between the grounding transformer and the artificial ground, the ground current is limited so that it can be left on long enough to take meter readings without damaging power equipment or interfering with the public telephone and telegraph circuits.

H. A. P. Langstaff: One advantage of the ground relay which has not as yet been mentioned is the reduction in duty on oil circuit breakers. The West Penn System, like all others, had breakers which were unable to withstand the duty to which they would be subjected unless some modifications were made, and the ground relay along with the neutral resistor was of considerable advantage. When relays were originally applied, we used overhead ground wires on all 25-kv. circuits, and the majority of line failures were to ground, meaning a large percentage to ground-relay operation. The installation of higher capacity breakers and the removal of overhead ground wires has shifted the percentage of failures to phase relays rather than ground relays.

The clearing of faults by means of the ground relay materially reduced system voltage disturbance. We have replaced the watt-relay by the directional relay, having two separate elements,—namely, the current element and directional element,—thereby allowing all ground relays to have the same characteristics and simplified settings.

Another point which has not been mentioned is the protection supplied for reserve bus breakers. All operating companies experience line failures when lines are operating on reserve bus breakers, thereby removing from service the balanced relaying schemes. This, of course, subjects the system to greater disturbances due to higher settings, and I believe that this should receive serious consideration by all operating companies.

As to the checking of ground relays, we used originally a phantom load for the watt-relay. Then we started to apply grounds to the system to check the selectivity of the watt-relay against current relays. After changing to relays of similar characteristics, we continued the ground application scheme of checking, but found that the phantom-load scheme was satisfactory, especially when we use the scheme mentioned by Mr. Sleeper, namely, diverting phase currents having known direction through the ground relay, and opening one leg of the potential transformers. Our field testing crews are obtaining very reliable results from this scheme of testing and the only time we apply

the ground is after an occasional faulty operation to check not only the ground relays but phase relays as well, in some cases.

G. H. Doan: I realize that there is a vast difference between the protection of a resistance-grounded system and that of a solidly grounded one. I should like to point out the scheme, however, that the Detroit Edison Company is using. In general, we have used for a number of years on all transmission lines—120-kv. and 24-kv.—a mechanically balanced differential relay. The operating experience with this for the past year has been in results, somewhere in the neighborhood of 98 and 99 per cent perfect.

This system is very advantageous, we think, in that it is almost instantaneous. Objection has been raised to the reduction of voltage at the time of fault. We realize that we do get voltage reduction at the time of fault, but we have found that if we can clear a fault quickly, we don't need to worry about the reduction. This relay has been doing it for some time.

Mention was made of low-energy relays. Again, we are different in that we believe that most of the relays furnished are not nearly sturdy enough and don't take nearly power enough, nor have sufficient force always to operate when you want them.

Manifestly, with a large system which is rather compact, it is rather difficult for us to see how we could go out and ground our lines for checking relays. As a matter of fact, I believe that our present check, made through the use of portable test transformers, (putting primary current through the current transformers as a current-transformer check and carefully tracing the potential-transformer circuits to the relays, added to a check on the relays as they are put into service to make sure that they are going in the right direction), has, so far, resulted in practically perfect connections. I cannot recall a single case of error of relay connections in the last two years. Unfortunately, we have had one or two cases of incorrect relay settings.

L. N. Crichton: The question has been raised as to the operation of ground relays on a system having its neutral dead-grounded.

The relay connection under consideration is the conventional one using a wattmeter type of relay, connected in the delta circuit of a bank of star-delta potential transformers. It happens that the voltage actually applied to the relay is the drop between the relay and the source of power, and consequently the phase relation between the current and voltage depends upon the characteristics of the power supply rather than the characteristics of the trouble.

When you take the resistance out of the neutral, the current lags far behind the voltage, and in addition, you get distorted phase relations due to unbalance in the voltage triangle, resulting in the current lagging more than 90 deg.; actual tests on a system showed 92 deg. Then, if you take into account other errors that are likely to creep in—unbalancing of potential transformers, and so on,—you will see that the relay has a poor chance of working correctly, if it is a true wattmeter. The trouble can be taken care of by making a relay which will work more efficiently on lagging current, and such a relay has recently been developed.

The question of removing the resistance from a number of systems is now under consideration and on those installations, the present relays can be kept in service by putting small phase-shifting devices on them.

The type of relay having its greatest torque with lagging current should be used, in general, on all systems, even those having a high resistance in the neutral, so that the installation will not require change if it should later be decided to remove the resistance.

J. Allen Johnson: (communicated after adjournment) I do not think that Messrs. Jones and Dodds intended to convey the impression that the use of "power relays with self-contained timing element" may not be entirely successful and satisfactory under some conditions, but such an impression may be created by their statement in the last paragraph of the first column on the second page of their paper.

The Niagara Falls Power Company has had in successful operation for several years on its 66-kv. circuits a system of ground protection using a specially designed low-energy power relay. The conditions here are very difficult as the neutral ground resistance may be as high as 750 ohms and the current transformers which supply current to the relays have a 600/5 ratio. Thus the ground-fault current may be as low as about 50 amperes, which may be divided over two parallel circuits, giving only about 25 amperes primary current in the current transformer or slightly over 0.2 ampere relay current.

The relays were designed to operate with 0.15 ampere with full voltage on the potential coil. Voltage for the relays is obtained from a potential transformer having a ratio of 34,500/115 connected directly across the 750-ohm neutral resistor. On account of the high neutral resistance, a very large proportion of the fault voltage always appears across the neutral resistance and potential transformer, and this resistance being practically non inductive, the voltage is always nearly in phase with the fault current. This results in very positive relay action.

The excellent operating record of this installation during the $3\frac{1}{2}$ years of its service is shown by the following record of operations.

	Ground relay operation on 66-kv. system			
	Correct	Desired	Incorrect	Undesired
1924	28	28	0	0
1925	28	28	0	0
1926	11	11	0	0
1927 (to June 20)	2	2	0	0
Totals	69	69	0	0

V. P. Brodsky: (communicated after adjournment) I should like to ask a question regarding the use and interpretation of the vector diagrams illustrating this paper. Subtractive-polarity current and potential transformers are used in the connection diagrams given in the paper. This may be seen from the polarity marks on these diagrams, and is also in accordance with the present standards.

In a subtractive-polarity transformer the primary (impressed) voltage is opposed in the internal circuit by the secondary (induced) e. m. f. This also applies to the currents.

However, in the external circuit, a subtractive polarity transformer does not introduce a change in polarity, which remains the same as if the transformers were not existing. It is therefore the reversed secondary voltage or reversed secondary current delivered to the relays which should be made use of in these applications.

I notice that in the vector diagrams given in the paper, the primary current is opposed by the secondary current, and the primary voltage by the secondary voltage.

I should like to ask whether the writers have considered the internal circuit of the transformers or the external circuit.

B. M. Jones: Mr. Sleeper asked about the use of the same relay for solidly grounded or resistor-grounded systems. I understand that one manufacturer has actually developed internal additions to present ground relays to cover just that field. This worried us considerably, too, as we contemplated grounding solid.

We very strongly favor actually grounding the systems for testing the directional ground relays. We have just finished the program of applying 305 grounds on our 22-kv. system to check 484 relays and found 17 field errors which our best inspectors couldn't find by any phantom method.

We have also finished a program of grounding our 66-kv. system to test the ground relays and found six incorrectly connected. We start about midnight and finish about four or five in the morning; we make 35 or 40 grounds a night. We have

the relay testers scattered over the system. It isn't very expensive and we feel that the expense is justified.

Mr. Johnson is right in assuming that the authors did not intend to convey the impression that the use of power relays with self-contained timing elements might not be entirely successful and satisfactory under some conditions. The statement made was that "the power relays have not proved satisfactory for ground protection due, primarily, to the fact that a sufficiently low-range relay has not been used."

The relay described by Mr. Johnson and used on the Niagara Falls Power Company System, operates on a very small number of watts and, as Mr. Johnson points out, the conditions on their system and their source of voltage for the relay are such that the voltage impressed on the relay under fault conditions is of a fairly high value; also, this voltage must be very nearly in phase with the fault current, thus insuring positive action of the relay.

The Niagara Falls Power Company's solution of its problem was very good, but this solution is not open to a great many power companies since many companies do not have ground connections at a large number of their stations.

As Mr. George of the Tennessee Electric Power Company points out, a great many of the points of difference are due to different operating conditions of various power companies. The scheme used by the Tennessee Company of getting its directional ground protection by the relative directions of two currents in the relay, one current being obtained from the line protected by the relay and the other from the grounded neutral of the power transformer bank, is a very cheap method of obtaining directional ground protection.

Again, however, this method is limited to those companies having their transmission systems grounded at their substations.

In regard to Mr. Brodsky's question as to whether the vector diagrams shown in the paper had reference to the internal circuit of the transformers or the external circuit, the vector diagrams, themselves, show only the phase relation existing between the current and potential on the relays, while the arrows in the relays indicate the instantaneous directions of the currents and voltages at a given time. For example, suppose we take the instant of time when a phase voltage is at a maximum, and assume that current is flowing out on the high-voltage line in the direction indicated by the arrows from the oil circuit breaker. Then, due to the subtractive polarity of the current transformer, the direction of current in the A-phase relay would be as indicated by the arrow. However, the voltage applied to this relay is the voltage from A-phase to C-phase, and since the instant of time was assumed when a phase voltage was at a maximum,, then the C voltage would be at about half maximum value, and A-phase, being at a higher potential than C-phase, the direction of potential would be from A to C in the external circuit.

The arrows and direction in the other two relays are also taken at the instant of time when that particular phase voltage is at its maximum value.

J. V. Breisky: Mr. Sleeper has asked whether the same relays could be used on systems grounded through resistance as on ungrounded systems? This can be done by somewhat changing the phase relations in the present design of relay, either by making changes internally or by means of external resistors and reactors as suggested by Mr. Sleeper. A relay could probably be developed which could be used interchangeably on these two types of systems since the limits of the phase position of the ground currents on both kinds of systems are quite well fixed. Of course this relay can be used on the ungrounded system only if the residual charging current is of sufficient magnitude to operate the relays as designed at present. It would be more satisfactory probably to dead-ground the system when it is necessary to remove the resistor and use a phase shifter to give correct operation (as mentioned by Mr. Crichton) with the present relay, which is designed to operate on systems grounded through resistance.

As pointed out by Mr. George, it is possible on systems grounded at every substation, through power or grounding transformers, to secure good ground protection by using relays operating on the product of the current through the transformer neutral and the line residual current. In this case, most of the ground current is supplied by the transformers adjacent to the grounded section and the relays may be operated on the inverse part of their curve to get good discrimination between the various sections. Such a relay is also directional, since the current through the transformer neutral always has the same direction, and it takes the place of voltage in serving as the reference quantity. Relays of this type have been used on the Pacific Coast with good success for several years and are being installed on several new jobs.

Certain types of over-current relays have slow-opening contacts. If, however, the fast-opening type is used with the directional contacts correctly spaced, I feel that the trouble mentioned by Mr. George, that of improper operations caused by closing of directional contact after over-current contacts have closed, will not be experienced. This could happen only after a breaker had opened, clearing a fault, and the flow of power had changed due to the distribution of load. If the over-current contacts are of the quick-opening type, they will be open by the time the directional elements close and the breaker will not operate. If for any reason the direction of power flow should change after a fault has occurred on a system and before it is removed, relays with a single element as well as those with separate over-current and directional elements would operate.

The trouble mentioned by Mr. George, of a load current of greater magnitude than the ground current preventing the reverse-power relay from operating correctly, can occur only when a non-directional ground relay is interlocked with directional elements operated by line current and voltage. The scheme outlined by Messrs. Jones and Dodds used when the system is solidly grounded with a suitable phase-shifting device as mentioned by Mr. Crichton, in which the relay is operated by residual current and voltage, is entirely independent of load currents.

Mr. George's statements that "the application of reverse-power relays on large transmission systems is apparently very limited and that reversal of power is an infrequent indication of trouble" are not quite clear to me. The reversal of power accompanied by an abnormal current is certainly an indication of trouble, and reversals unaccompanied by over-current will not cause operation of relays. There are thousands of relays of this type giving satisfactory service and in many cases it is the only type which will give the necessary protection.

The scheme of using mechanically balanced relays, as mentioned by Mr. Doan, is, in general, very satisfactory except that its use is limited to cases where there are enough lines in parallel so that there will always be at least two left under any operating condition. Such cases are not common except in large urban cable systems. Undoubtedly, as Mr. Doan points out, it would be desirable to use relays which would take more power to operate but which would be more positive in their operation. Unfortunately, however, the demand seems to be for a relay that will require less and less power to operate it except possibly on large cable systems where a large amount of power is concentrated into a relatively small area. So far as sturdiness is concerned, however, we seldom hear of the mechanical failure of a relay.

In answer to Mr. Brodsky's question regarding the vector diagrams, I should like to mention that it does not matter whether the secondary quantities are shown reversed or not, since this will affect both current and voltage similarly and the phase relations will remain unchanged. Although vector diagrams are not entirely standardized, I believe the line quantities and the relay quantities are usually drawn in the same direction when subtractive polarity transformers are used since this is in line with the idea that the transformers may be considered as straight-through connections.

The Electric Arc

BY K. T. COMPTON*

Non-member

***Synopsis.**—DEFINITION OF ARC. An arc is a discharge of electricity, between electrodes in a gas or vapor, which has a voltage drop at the cathode of the order of the minimum ionizing or minimum exciting potential of the gas or vapor.*

ARC CHARACTERISTICS. The relation of arcs to glow discharges and coronas is illustrated by discussion of "generalized" curve of the gas discharge characteristic. Empirical equations for arc characteristics are interpreted, and a dependence on the boiling temperature of the anode is shown. Seeliger's experiments on the transition from glow to arc, accompanied by the development of a cathode spot, show that the mechanism of the current at the cathode is fundamentally different in the two types of discharge.

CATHODE SPOT. An analysis based on heat conduction in the cathode shows that the cathode spot has no sharp thermal definition, but does have a sharp boundary if defined by visual brightness or by thermionic emission. The phenomenon of moving cathode spots presents the problem of accounting for the observed temperatures.

THEORIES OF CATHODE FALL. Compton's theory is based on space charge considerations and the assumption that the thickness of the fall space is equal to the electronic mean free path. Langmuir's theory differs from Compton's in assuming this thickness to be considerably less than a free path. Considerations of energy balance at the cathode definitely support Langmuir's rather than Compton's theory.

ENERGY BALANCE AT CATHODE. Calorimetric measurements permit an estimate of the fraction of the current at the cathode which is carried by electrons. Though uncertain, the data are accurate enough definitely to support Langmuir's theory and to indicate that, in many cases, thermionic emission of electrons from the cathode is supplemented by a "pulling out" of electrons by the electric field which is concentrated at the cathode surface.

Factors which determine the anode drop and the potential fall and ionization in the negative glow and the positive column are briefly discussed.

In the brief space at the writer's disposal, it is impossible to treat the subject in a comprehensive manner and there will therefore be discussed principally certain recent developments which have added much to our understanding of the processes involved in arc discharges.

Definition of Electric Arc

One is struck, in reading the literature of this subject, at finding no precise definition of an arc. This is due to the fact that, although we readily distinguish common forms of arcs from sparks, glow discharges, and coronas, yet there are gradations from one form to another so that the distinction is sometimes difficult to make. Child[1] describes an arc as "a continuous current of several amperes or more, passing through a gas and having a cathode drop which is comparatively small." Hagenbach[2] says, "In order to be able to define the arc, the cathode fall must be taken to be characteristic. As compared with the glow discharge, it is small . . . ."

The arc is characterized by a larger current and a lower voltage than any other type of gas discharge. It is generally obtained in gases or vapors whose density, at the cathode, corresponds to a pressure of the order of a millimeter of mercury, or more. Every arc has a region of luminous gas near the cathode. Whether or not there is another region of luminosity, the positive column, depends on the gas pressure, the distance from the cathode to the anode, the current, and the shape of the containing vessel if the arc is enclosed. High pressure, large distance, and constricted container favor the appearance of the positive column in an arc. The total voltage across the arc is the sum of (1) the cathode drop, which has a value characteristic of the gas; (2) the anode drop, which depends on the size and shape of the anode as well as the nature of the gas and its degree of ionization, and which may be positive or negative in sign; (3) the drop along the positive column, which is generally proportional to the length of the positive column and depends on the current and the nature and density of the gas; (4) a voltage drop, generally negative but usually small, between the region of the cathode fall and the beginning of the positive column. Of these parts it is only the cathode drop which appears to have a definite characteristic value; the other three may be altered by altering the current, the pressure, or the geometry of the arc path. Hence the total arc voltage is not particularly significant, although it may be considered as a characteristic parameter if the arc conditions are specified as, for example, an arc between plane parallel electrodes of large extent, with more than a minimal separation, and placed in a gas at a given pressure. The volt-ampere characteristics of an arc is generally negative, *i. e.*, the voltage across the arc falls as the current is increased. It may, however, be zero (voltage drop independent of current) as would be the case if the cathode drop constituted the entire voltage drop in the arc. Probably a slight positive characteristic could be obtained in an arc whose anode is of very small dimensions and is located within the region of negative glow just beyond the boundary of the cathode fall space.

In view of these considerations, which will be amplified later, the following definition of an arc is proposed: *An arc is a discharge of electricity, between electrodes in a gas or vapor, which has a voltage drop at the cathode of the order of the minimum ionizing or minimum exciting potential of the gas or vapor.*

*Professor of Physics, Princeton University, Princeton, N. J.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

remembered, however, that there are s between typical arcs and typical glow h cannot be defined as either. These es are generally extremely unstable, so eldom encountered in practise. Unless igh series resistance and a correspond-e of e. m. f. are used, the transition from from arc to nothing is abrupt and these s are not obtained.[3]

E CHARACTERISTICS AND TYPES OF DISCHARGE

of the arc to other types of gas discharge d by the generalized discharge character-nplest gas discharge circuit consists of a f., E, a discharge between electrodes, D, sistance, R, together with an ammeter er to measure the current i and the

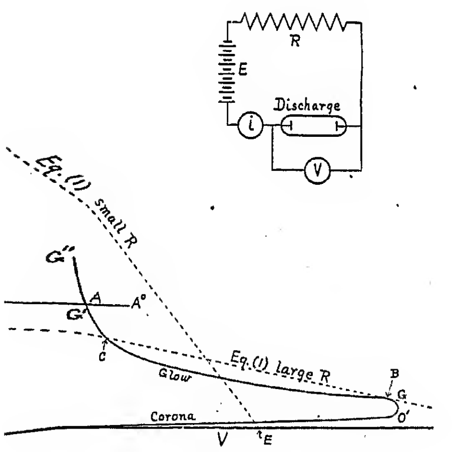

FIG. 1

V across the discharge. The external eristic is obviously

$$E = V + R\,i. \tag{1}$$

he discharge apparatus itself is given by racteristic

$$V = f\,(i)\,. \tag{2}$$

xternal characteristic is represented by a f slope $-1/R$ and voltage intercept E. aracteristic is represented by the curve '. The possible values of current and ven by the intersection points of these (2).

constant, E is gradually increased from O, the current is first small and the volt-teristic is positive. This is the region of wnsend currents $O\,O'$. Beyond O' the increases, the volt-ampere characteristic is negative and we have the region of the glow discharge $G\,G'$. The current jumps discontinuously from point B to point C on the curve. Obviously, the entire glow discharge may be skipped over if the resistance R is small, *i. e.*, the slope of the line $E\,B\,C$ large. In this case the discharge passes abruptly from the corona to the arc type. On the other hand, if the resistance R is very large and the line $E\,B\,C$ almost horizontal, the entire change from corona through glow to arc may be passed through continuously.

At $G'\,A$ there is a transition from glow to arc. Sometimes this transition is gradual and sometimes abrupt, in which cases the curve is rounded or sharp at the transition region $G'\,A$. If the transition is abrupt, there is evidence that the glow and arc characteristics intersect and may be prolonged as $G'\,G''$ and $A°\,A$, and it is then possible to have either an arc or a glow discharge at the same voltage, or at the same current, and we have, within a small range, the anomalous situation of a glow discharge carrying larger currents than the arc at the same voltage.

In general, it is possible to determine the entire discharge characteristic of any given type of discharge apparatus by using sufficiently large ballast resistance, R, and correspondingly large e. m. f., E. Once this characteristic is known, the various changes in the discharge, which will be found when any variations of E or R are made in the circuit, may be predicted.

In this connection, mention only may be made of a very complete discussion of the question of *stability* of gas discharges given by Dallenbach[5] and summarized by Bär[6]. The fundamental condition for stability[7] is that $-\dfrac{d\,V}{d\,i} < R$, *i. e.*, that the slope of the internal characteristic curve (2) be greater than that of the external characteristic curve (1). In addition to this, inductance and capacity and inertia of ions must be taken into consideration.

EQUATIONS OF THE ARC CHARACTERISTIC

Several empirical equations have been proposed to describe the current-voltage characteristics of arcs. The best known of these are

Frolich[8] $$V = a + b\,l \tag{3}$$

Ayrton[9] $$V = a + b\,l + \frac{c + d\,l}{i} \tag{4}$$

Steinmetz[10] $$V = a + \frac{c\,(l + d)}{\sqrt{i}} \tag{5}$$

These may be interpreted as follows. The constant term a is the sum of the cathode and anode drops. The term $b\,l$ is the voltage drop in the positive column, whose length is taken to be equal to the total arc length l. The terms involving current i in the denominators

of (4) and (5) take care of the negative characteristic feature of the arc. In (4) the term c/i involves the negative characteristic of the negative glow and perhaps of the anode drop, while the term $d\,l/i$ gives the negative characteristic of the positive column. These same features are described somewhat differently in (5). In any case, these equations are known to be only empirical approximations.

Recently Nottingham[11] has shown that a new equation

$$V = A + B/i^n \qquad (6)$$

is very accurate for all the large number of arcs tried,

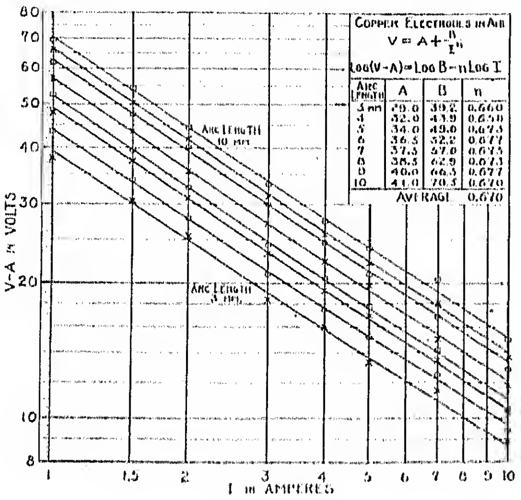

Fig. 2

provided one of the electrodes, usually the anode, reaches a definite temperature which is usually fixed by its boiling point. In this case, n is found to depend on the boiling temperature T of the metal through the relation

$$n = 2.62\,(10)^{-4}\,T \qquad (7)$$

and A and B are constants for a given metal and arc length. The experimental determination of n is illustrated by the case of copper, Fig. 2. Here V and i are plotted logarithmically, so that n is given by the slope, which is seen to be the same for all arc lengths. The accuracy of relation (7) over the entire range of arc temperatures is shown by Fig. 3. Recent unpublished work has extended this curve to cadmium at $T = 1051$ deg. K. The significance of this dependence of n on the maximum electrode temperature is not yet understood, but the fact cannot be doubted.

Fundamental Importance of Phenomena at Cathode

All lines of evidence indicate that the essential feature of an arc is the emission of electrons from the cathode which produces sufficient ionization of the surrounding gas to give a positive space charge just outside the cathode, thus facilitating ionization and permitting a large, generally saturation, electron emission at relatively low voltage. All other characteristics of arcs appear to be either consequences of this emission or prerequisites to it under the particular physical conditions in which the arc is produced. Thus it is possible to produce arcs in which the anode drop in potential is practically eliminated, in which the potential gradient in the gas is nearly zero or is reversed, in which there is no chemical action or consumption of the electrodes, or in which the gas or anode temperature is low. The cathode drop and its emission of electrons are indispensable, however. Theoretically *any* mechanism or process for supplying electrons from a cathode in sufficient numbers to produce, at low voltages of the order of the minimum critical potentials of the gas, enough ionization to give a positive space charge should suffice to maintain an arc. Actually, however, only two emission processes seem capable of supplying electron emission in sufficient amount: thermionic emission and the pulling of electrons from the cathode by the large field in the cathode fall space, or a combination of these two. J. J. Thomson[12] and Stark[13] first suggested the former theory and Langmuir[14] the latter one. The present evidence, some of which we shall now review, points to the truth of each in particular cases, and generally to a combination of both. We shall proceed, therefore, to an examination of the conditions at the cathode.

Cathode Spot: Area, Temperature, Current Density

In all arcs, except those in which the cathode has small area and cannot lose heat rapidly by metallic conduction (as in arcs with hot filament cathodes as used in Tungar rectifiers) the current at the cathode is concentrated in a small area which is generally called the "cathode spot." To study the physical condition

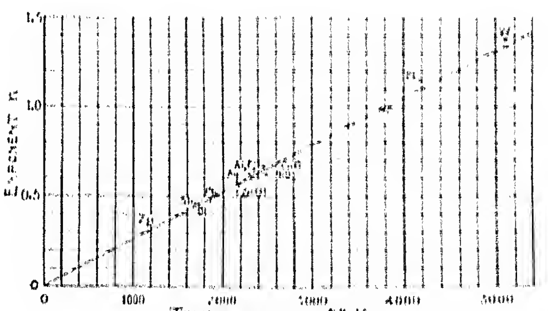

Fig. 3

of the cathode, we must therefore examine this cathode spot. This is extremely difficult, however, owing to its small size, its frequent rapid motion, and the difficulty in defining it. Until very recently there were no measurements of the area of the cathode spot except in the case of carbon arcs, but recently measurements also have been made on several metallic arcs. These results are shown in Table I.

In the case of carbon, the spot is stationary and the chief source of error is probably in the measurement of the photographic plate, owing to photographic broadening with overexposure and to failure to use reliable methods in correlating distribution of photographic

density with intensity of light. It should be remarked, moreover, that different grades of carbon give different results, presumably due to the effect of alkaline impurities on the amount of thermionic emission. In the metal arcs, the spot usually wanders rapidly, so that Güntherschulze photographed it as a band after reflection from a revolving mirror. Seeliger[15] was unable to repeat Güntherschulze's work. Nottingham has used

TABLE I

an accurate photometric method of measuring his photographic plates, but did not use a revolving mirror; the internal evidence in his work, however, justifies considerable confidence in its correctness.

Similarly, the temperature of the cathode spot is not very accurately known. The best determination for carbon arcs is probably that of Reich[16], who gives 3413 deg. K, although other observers give values from 2903 deg. K. to 3593 deg. K[17]. Hagenbach and Langbein[18] give for iron 2430 deg. K., nickel 2365 deg. K., tungsten 3000 deg. K., silver and copper below 1800 deg. K. Nottingham, however, has found fusion of tungsten in the cathode spot, which would prove its temperature to be at least 3643 deg. K. It is quite possible that the small size of cathode spots has led to an underestimate of their maximum temperature.

The cathode spot of a mercury arc has been estimated as between 2000 and 3000 deg. K. on account of a continuous spectrum emitted from it and ascribed by Stark[13] to local high temperature, in spite of the much lower boiling temperature of mercury, thus supporting his theory of the thermionic origin of the electron emission from the cathode. This spectrum, however, is not characteristic of so high a temperature and may be otherwise accounted for, and there is no certain evidence that the temperature is so high. Seeliger[15] applied Knudsen's equation to rate of evaporation as a function of temperature, using Güntherschulze's measurements of rate of evaporation[18], and calculated a lower limit of 673 deg. K. We shall present evidence below, however, indicating that the mercury loss measured by Güntherschulze was partly in the form of a spray rather than true evaporation, so that Seeliger's lower limit should be considerably less than 673 deg. K. Thus we really know very little regarding the temperature of the cathode spot in mercury arcs.

A very illuminating study of the theory of the cathode spot has been made by Seeliger[15]. Consider first a case where heat is liberated at a rate Q per cm.^{2} at a fixed circular area A on the plane surface of a metal block of indefinite extent. This corresponds roughly to the heated region of a cathode surface. Because of heat conduction in the metal, a temperature gradient is set up radially outward on the surface of the block as well as into its depth. The final steady surface temperature distribution is calculated by the known theory of heat conduction and is found to be of the form shown by the curve T, Fig. 4A. It is quite obvious that there is nothing in the nature of a sharply defined "hot" spot.

The spot is observed, however, by means of the light radiation from it, and it is well known that visual brightess L increases as a high power of the temperature T, being given approximately by the relation

$$T = \frac{11230}{5.367 - \log L} \tag{8}$$

in the temperature range involved here. From this,

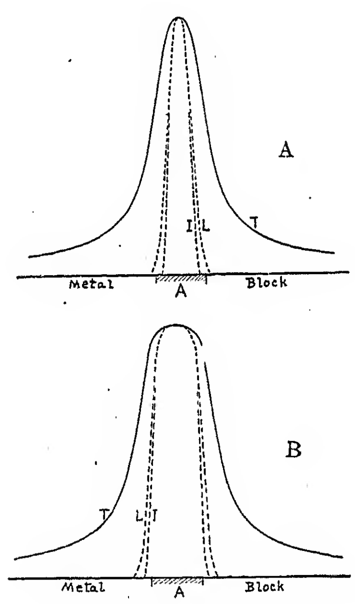

FIG. 4

and assuming that the maximum temperature in curve T, Fig. 4A, is 3300 deg. K., the visual brightness curve L is found to be as shown. This does limit quite a sharply defined region, which does not differ much in area from A. Thus, as seen by the eye, the cathode spot is sharply defined.

Electrically, however, it is neither the temperature nor the brightness, but the thermionic emission which is important, and this may be calculated as a function of temperature by Richardson's equation

$$I = A\, T^{1/2}\, \epsilon^{-b/T} \tag{9}$$

Taking $b = 6\ (10)^4$ for carbon, this leads to curve I for the current density of thermionic emission from various regions of the spot. Here again the spot is quite sharply defined and has approximately the dimensions of A, although it is somewhat smaller than the "visual" spot.

It is certain that considerations such as these are involved in stationary cathode spots, especially if the electron emission is primarily of thermionic origin. The problem is further complicated, however, in cases where evaporation or sublimation tends to cool the cathode, and of course electron emission is itself a cooling process. Thus these cooling agencies, acting in addition to conduction through the body of the cathode, must tend to limit the temperature in the hottest regions of the spot, and thus to alter the distributions of Fig. 4A to something like the form of Fig. 4B, which helps to explain the fact that the area of the spot is so nearly directly proportional to the current.

In the case of metallic arcs whose spot wanders rapidly over the cathode surface, there is a real difficulty in explaining the high temperature of the spot, since the time available for heating is very short. In a mercury arc, for instance, the spot frequently wanders at a rate of at least 300 cm. per sec.[19, 20] and may move 30 times this fast. Güntherschulze[21], Stolt[20], and Seeliger[15] have attempted to calculate the maximum possible rise in temperature if all the energy $i\,V_c$ liberated at the cathode goes into the metal and is carried away by heat conduction into the body of the cathode. Both calculations are rough approximations and they lead to opposing conclusions; *i. e.*, Güntherschulze concludes that the cathode spot even in mercury arcs rises to temperatures above 2000 deg. cent., while Seeliger and Stolt conclude that the temperature rises to only a few hundred degrees in mercury and copper arcs. The evidence is that Güntherschulze's conclusion is right, for at least in copper the metal is found to be fused where the hot spot passes, although both Seeliger and Stolt criticize his computations. It is difficult to estimate the value of these computations, not only because of uncertainty regarding the data and the constants (such as heat conductivity at elevated temperatures) but also because the spot may not wander continuously, but jump from point to point, remaining at each point long enough to heat it.

It is evident from this brief survey that, in spite of the attention which has been focussed on the cathode spot since its crucial importance in the theory of the arc has been realized, there is as yet no agreement as to whether the cathode spot *always* reaches such temperatures as to warrant a purely thermionic explanation of the electron emission from it.

Thermionic Emission from the Cathode

Table II gives thermionic emission values calculated from Richardson's equation (9). In comparing these values with current densities at the cathode spot in arcs, certain facts should be kept in mind. The emission values for carbon were given by Langmuir[22] for carbon as pure as could be obtained and with great care to avoid contamination. Such purity is utterly impossible in arc carbons, and the impurities which are known to be present are such as to increase the emission very considerably. An upper limit for arc carbons would be the values given for lime-impregnated carbon[23]. The actual thermionic emission from an arc carbon must lie between the values 26.7 and 4400 amperes per cm.[2] Further than this we cannot say at present. But this makes it evident that much, and possibly practically all, of the arc current, see Table I, is simply thermionic emission of electrons from the cathode. Similarly, in the case of the tungsten arc in air, the thermionic emission at the temperature of the cathode spot is adequate to account for the arc current, if Nottingham's values are correct.

TABLE II

Carbon $A = 1.49\,(10)^{25}$ $b = 48{,}700$		Impregnated carbon $A = 3.3\,(10)^{26}$ $b = 42{,}000$		Tungsten $A = 1.55\,(10)^{26}$ $b = 52{,}500$	
T deg. K.	Amps. per cm.^{2}	T deg. K.	Amps. per cm.^{2}	T deg. K.	Amps. per cm.^{2}
2700	1.0	2700	500	2400	0.365
3000	13.2	3000	2390	2800	8.98
*3140	26.7	*3140	4400	3200	96.9
3300	54.7			3540	509
3500	127			*3640	977

The most accurate identification of arc current with thermionic emission from the cathode is obtained in arcs from a small non-vaporizing cathode, such as in Tungar rectifiers or Pointilite lamps in which there is no "hot" spot, but the entire cathode is at practically uniform temperature. In these cases, the temperature may be measured with an optical pyrometer and the thermionic emission current rather accurately estimated. In such cases, the arc current is generally found to be accounted for by thermionic emission[24], although in very intense arcs in gas at high pressure the arc current is somewhat larger than the calculated thermionic emission.

In the case of arcs from more easily volatilized cathodes the data, as we saw above, are too uncertain to support any very positive statement regarding the adequacy or inadequacy of thermionic emission in accounting for the arc currents. On the whole, the writer is inclined to the opinion that in these cases, as well as in the intense high pressure arcs above, the ordinary thermionic emission is increased by an effect of the intense electric field at the cathode in actually *pulling electrons away from the cathode* which would not otherwise be emitted. This theory, due principally to Langmuir, is discussed later. It is significant that some agency in addition to thermionic emission appears to be needed to account for arc currents in just those cases in which conditions for such a "pulling out" effect would be most anticipated.

Development of an Arc

Seeliger[25] has recently made an instructive experiment on the development of an arc from a glow discharge, and the relation of this to the formation of the cathode spot. He used a very high resistance

to stabilize the discharge and very pure electrodes, and followed through the variations in current density as the total discharge current was increased, beginning with a normal glow discharge covering only part of the cathode. The results are shown diagrammatically in Fig. 5.

In interval, $a\,b$, the current density was constant, the cathode fall of potential was constant at about 300 volts, and the glow did not completely cover the cathode. At b, the glow completely covered the cathode. Further increase in current was accompanied by increase in current density and large increase in the cathode drop, which may rise to several thousand volts. At c there was first observed a tendency for the cathode glow to concentrate into a hot spot, which tendency increased with further increase in current. Simultaneously the current density increased at an accelerated rate, while the cathode drop began again to diminish. At the point d, the cathode drop had fallen to a value less than the original normal cathode drop, and it was falling so fast and the current density was rising so fast that the series resistance was insufficient to stabilize the discharge and it passed abruptly to condition e, from which point on the discharge was a true arc, the glow was replaced entirely by the hot spot, and the cathode drop was in the neighborhood of 10 volts.

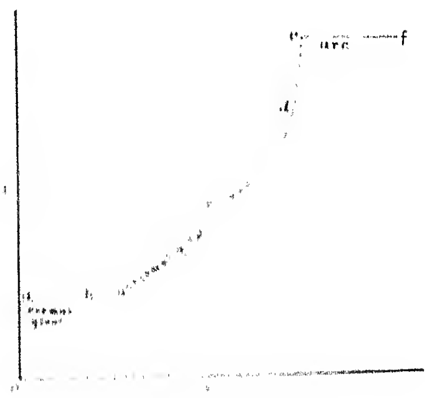

FIG. 5

This illustrates the fact that the mechanism of current transfer in the glow and arc discharges is quite different. In the glow discharge the current at the cathode is carried principally by positive ions, and the electron emission from the cathode is "secondary" emission due to positive ion bombardment and photoelectric action. In the arc discharge the current at the cathode is carried principally by electrons, which are probably liberated thermionically, assisted by the "pulling out" action of the field. The thickness of the cathode fall space in the arc is certainly thousands of times smaller than that in the normal glow discharge.

Qualitatively, the progressive stages in the development of an arc may be "explained" by the principle that *the potential distribution in a gas discharge adjusts itself so as to give maximum current, subject to the limitations imposed by Poisson's equation.* This principle appears to be new in the theory of gas discharges and has recently been applied with success to the theory of the normal glow discharge[26]. Further applications of it should be attempted.

Compton's Theory of Current at Cathode[27]

The existence of the cathode fall of potential is proof that the space charge near the cathode is positive, *i. e.*, that the concentration of positive ions exceeds that of electrons. Let i be the electron current density and $J + j$ be the positive ion current density. j is that part of the positive ion current which just neutralizes the space charge of the electrons, and J is the excess, which accounts for the positive space charge, whose density we shall call ρ. By Poisson's equation,

$$\frac{d^2 V}{d x^2} = -4 \pi \rho = -4 \pi \frac{J}{v}, \tag{10}$$

where v is the average velocity of advance of the positive ions in the field $- d V/d x$. If this field were uniform, and if the ion made numerous collisions with atoms, and if these collisions were either "head on" or inelastic, v would be given in terms of ionic charge e, mass M and mean free path L by [28]

$$v = \sqrt{\frac{\pi}{2}} \sqrt{L \frac{e}{M} \frac{d V}{d x}}. \tag{11}$$

If we consider the impacts to be elastic, not all "head on," but rather as if made by a sphere moving under constant force among similar spheres distributed at random, the factor $\sqrt{\pi/2}$ changes to very nearly $.96\sqrt{2}$[26], which is a little larger. If, however, the field is not constant, but is increasing toward the cathode, as is almost certainly the case, this factor is less, but cannot be less than $.96\sqrt{2}/\sqrt{2}$ and is certainly much nearer the higher value if the positive ions make at least two or three collisions while traversing the cathode fall space. With these uncertainties in mind, we cannot be far wrong if we take equation (**11**), as was done in the original publication of the theory.

Substituting for v in equation (**10**) from equation (**11**), and integrating, we obtain

$$\left(\frac{d V}{d x}\right)^{3/2} = \frac{3}{2} B J x + C_1, \text{ where } B = 4 \pi / \sqrt{\frac{\pi}{2} \frac{e}{M} L}. \tag{12}$$

The integration constant C_1 is determined by the condition that $d V/d x = 0$ at the outer boundary of the cathode fall space. Taking $x = 0$ at the cathode surface and $x = c$ at the boundary of the fall space, we have

$$\frac{d V}{d x} = \left[\frac{3}{2} B J (c - x) \right]^{2/3}.$$

Integrating again, and putting $V = 0$ when $x = 0$, $V = V_c$ when $x = c$, and solving for the cathode fall of potential, we have

$$V_c = \frac{3}{5}\left(\frac{3}{2}\,B\,J\right)^{2/3} c^{5/3}.$$

Resubstituting the value of B from equation (12) gives

$$V_c = \frac{3}{5}\,\frac{(6\,\pi)^{2/3}\,J^{2/3}\,c^{5/3}}{\left(\frac{\pi}{2}\,\frac{e}{M}\,L\right)^{1/3}} \tag{13}$$

We are entirely without experimental evidence regarding the thickness of the cathode fall space in arcs, except for the knowledge that it is extremely small. It seems certain that it does not exceed the electronic mean free path l, since the electrons have their best chance to ionize at their first impact owing to the fact that electric intensity diminishes with distance from the cathode. In the present theory it is assumed that $c = l$, though it may be that this is an upper limit. Now the ionic free path L is $\sqrt{2}$ times the molecular free path λ, since the ions have a higher order of speed than do the molecules. Also, the electron free path l is $4\sqrt{2}$ times λ, and hence 4 times L, owing to the negligibly small dimensions of an electron. Thus, writing $c = l$ and $L = l/4$, and solving equation (13) for J, we find

$$J = \frac{1}{12}\left(\frac{\pi}{2}\,\frac{e}{M}\right)^{1/2}\left(\frac{5}{3}\,V_c\right)^{3/2}\frac{1}{l^2} \text{ in c. g. s. units.}$$

$$= 0.76\,(10)^{-7}\,\frac{V_c^{3/2}}{M^{1/2}\,l^2}$$ in amperes per cm.², with M in ordinary molecular weight units. (14)

If c in equation (13) should have been taken to be less than l, then J would be larger than calculated by equation (14).

Consider now that part of the positive ion current density j required to neutralize the electron space charge. An exact calculation of the relative times required for an electron and a positive ion to pass through the fall space appears impossible, but the following approximation is probably accurate enough for the present purpose. Assume first that the field in the fall space is uniform and hence equal to V_c/l. The time t required for an electron, starting from rest at the cathode, to traverse the fall space is given by

$$l = \frac{1}{2}\,a t^2, \text{ where } a = \frac{e\,E}{m} = \frac{e\,V_c}{m\,l}, \text{ whence}$$

$$t^- = l\sqrt{\frac{2\,m}{e\,V_c}}\,. \tag{15}$$

The positive ions, on the other hand, move forward with average velocity given approximately by equation (11). Putting $d\,V/d\,x = V_c/l$, and $L = l/4$, and taking the time t^+ as distance l divided by mean velocity v, we have

$$t^+ = l\sqrt{\frac{8}{\pi}\,\frac{M}{e\,V_c}}\,. \tag{16}$$

Since $j = n^+ e\,v^+$ and $i = n^- e\,v^-$, and since $n^+ e = n^- e$ for exact compensation of space charge, we have

$$\frac{i}{j} = \frac{v^-}{v^+} = \frac{t^+}{t^-} = \sqrt{\frac{4}{\pi}\,\frac{M}{m}}\,. \tag{17}$$

In the actual case, however, the field is not constant but varies from a maximum value at $x = 0$ to zero at $x = l$. Thus the electrons always move faster and the positive ions slower than we have assumed, and the ratio i/j is larger than the value given by equation (17). A graphical integration, using the actual field distribution as given by equation (12) to find t^- and t^+, led to a value of i/j not much different from

$$\frac{i}{j} = 4\sqrt{2}\sqrt{\frac{M}{m}}\,. \tag{18}$$

which was the relation taken in the original statement of the theory[27], but derived there in a manner quite inconsistent with the actual physical conditions in the fall space. We shall use equation (18), therefore, in the belief that it is at least a fair approximation to the requirements of the theory.

Expressing currents in amperes, potential drop in volts and ionic mass M in ordinary atomic units, we have the results of this theory expressed by the equations:

$$\left.\begin{array}{lll} \text{Total current density} & I = i + j + J & \\ \text{Neutralizing current density} & i = 242\sqrt{M}\,j & \\ \text{Space charge current density} & J = 0.76\,(10)^{-7}\,\dfrac{V_c^{3/2}}{M^{1/2}\,l^2} & \end{array}\right\} \tag{19}$$

Applications: Carbon Arc. At atmospheric pressure and 3300 deg. $K.$, which is close to the cathode temperature $l = 0.66\,(10)^{-3}$ cm., V_c is given as about 8.6 volts[29], although no determination by a reliable method has ever been made, and the true value is probably several volts higher. Substitution in equation (19) gives $J = 1.6$ amperes per cm.² Since the total current density I is of the order of 320 amperes per cm.²,[30] $J/I = 0.005$. Similarly $j/I = 0.001$. Thus altogether about 0.006 of the total current is carried by positive ions.

Mercury Arc. The vapor density at the cathode is of the order of an atmosphere[31] and its temperature is at least 400 deg. $K.$, and may reach 2000 deg. $K.$, although reasons are given later which weigh against this high value. We shall not be far wrong as to order of magnitude if we take 600 deg. $K.$, which gives $l = 0.000040$ cm. V_c lies between 5.5 and 10.3, and is probably about 8.6. This leads to $J = 162$ amperes per cm.² Güntherschulze finds the current density I at the cathode to be 4000 amperes per cm.², whence $J/I = 0.040$. Similarly $j/I = 0.0003$. Thus about 0.04 of the total current is carried by positive ions.

Other cases agree in indicating that only a small

fraction of the total current at the cathode is carried by positive ions.

A test of this theory is afforded by comparing these calculated values for the fraction of current carried by positive ions with the values calculated from considerations of thermal equilibrium at the cathode. Before doing this, however, we shall consider an alternative theory of the cathode fall space which has been proposed by Langmuir.

Langmuir's Theory of Current at Cathode[14]

On this theory, the cathode fall space is simply the positive ion sheath produced around the cathode by the incoming positive ions. If it is assumed that the positive ions traverse this fall space without colliding with gas molecules, *i. e.*, if $d < l$, the space charge equation of Child[32] and Langmuir[33] may be applied in the form,

$$J = \frac{\sqrt{2}}{9\pi}\sqrt{\frac{e}{M}}\,\frac{V_c^{3/2}}{d^2} \text{ in c. g. s. units}$$

$$= 0.543\,(10)^{-7}\,\frac{V_c^{3/2}}{M^{1/2}\,d^2} \text{ in ordinary electrical and molecular units.} \quad (20)$$

This does not appear to differ much from equation (19) of Compton's theory, but in reality it may be quite different since it does not assume d to be equal to the electron free path l, but leaves d undetermined. In order to use this equation, information from some other source must be obtained regarding either J or d.

Two courses are open for finding independently the positive ion current density, $J + j$, in order to test Compton's theory or to complete the information necessary for Langmuir's theory. $J + j$ may perhaps be measured directly by Langmuir's exploring electrode method[34], although this has never been done near the cathode and presents experimental difficulties, or $J + j/I$ may be calculated from considerations of thermal equilibrium at the cathode, as follows:

Energy Balance at Cathode[35]

Let f be the fraction of the current at the cathode which is carried by electrons and $1 - f$ that carried by positive ions. Then, per ampere of current, we have the following rates of heat development, in watts:

A. *Heating of Cathode.* (1) By incoming positive ions, which fall through the cathode drop V_c, $(1 - f)(V_c + \varphi_+)$, where φ_+ is the heat of neutralization of positive ions at the surface of the cathode; (2) by outgoing electrons, some of whose energy may be returned to the cathode, $[f(V_c - (1 - f)\,V_i]\,F$; here $f\,V_c$ is the energy gained by the electrons in the cathode fall space, $(1 - f)\,V_i$ is the energy of these electrons which is used in ionizing the gas whose ionizing potential is V_i, and F is the fraction of the remaining energy which returns to the cathode in the form of radiation, etc.; (3) by heat supplied by an external heating source, if there be one, H.

B. *Cooling of Cathode.* (1) By escape of electrons, $f\,\varphi_-$, where φ_- is the electron "work function," or heat of evaporation; (2) by conduction through the body of the cathode, C; (3) by gaseous conduction and convection, C'; (4) by radiation, R; (5) by evaporation of cathode material, E.

Grouping all these items, we find the equilibrium condition to be given by

$$f = \frac{V_c + \varphi_+ - F\,V_i + H - C - C' - R - E}{V_c + \varphi_+ + \varphi_- - F\,(V_c + V_i)} \qquad (21)$$

An experimental determination of the factors in this equation should therefore permit a calculation of the fraction f of the current at the cathode which is carried by electrons. Let us consider the various terms in this equation:

The cathode fall of potential V_c in various arcs has been measured with the following typical results:

TABLE III

Arc	V_c (volts)	Reference
Carbon in air (current I)	$7.6 + 13.6/I$	(24)
Carbon (impregnated) in air	8.5	(31)
Magnetite in air	13.9	(32)
Copper in air at reduced pressure	13.7	(32)
Mercury in vacuum	5.27	(33)
*Argon gas and heated non-vaporizing cathode	11.6	(34)
*Helium gas and heated non-vaporizing cathode	20.0	(35)
*Mercury vapor and heated non-vaporizing cathode	5.5	(35)

As all values except those marked * were obtained by the old probe method which is known to give incorrect results[34], they are only approximate and are probably several volts too low. More accurate values are greatly needed.

The heat of neutralization, or condensation, of positive ions φ_+ was formerly calculated from a theoretical relation $\varphi_+ = V_i + L - \varphi_-$ derived by Schottky and von Issendorff[41] and by Compton[35]. Recent experimental measurements[42] have shown that the true value is much less than this, and nearly zero. The discrepancy must be due to the fact that some of the energy liberated at the electrode surface during neutralization of an ion is radiated away and hence does not contribute to the heating of the electrode. Compton and Van Voorhis[43] give reasons for modifying the above equation to the form

$$\varphi_+ = r\,V_i + (L) - \varphi_-, \qquad (22)$$

where r is a "radiation factor" a little less than 0.5, and L is the latent heat of condensation of the neutralized ion on the electrode, in case the ion remains there deposited. If the material of the ion does not remain on the electrode after neutralization, L is to be omitted from equation (22).

In this connection, the writer would suggest that the luminosity of the cathode in mercury arcs, which has been taken to indicate high local temperatures exceeding 2000 deg. $K.$, may be simply this radiation accompanying ion neutralization at the cathode surface,

and showing as a continuous spectrum because of the intense field at the surface. Evidence that electron emission in this case is not of ordinary thermionic origin will be presented below.

The ionizing potential V_i is accurately known for most gases and vapors. In the case of arcs in air between vaporizing electrodes, there is uncertainty regarding the type of gas which is being ionized.

The fraction F of the excess energy of the electrons which is returned to the cathode is unknown. It cannot exceed 0.5. It is probably much nearer 0.0, expecially in the case of a rapidly vaporizing cathode, where a blast of atoms would tend to carry away any high speed atoms which might have been indirectly accelerated by the electrons. Radiation of energy back to the electrode from the gas would be a small positive factor.

H, C, C', R, and E may all be measured or computed. In considering the cooling E by evaporation of cathode material, one must be cautious, however, since there is evidence in cases like the mercury arc that not all material lost is by true evaporation, but part of it is by mechanical loss as a "spray" which does not contribute to the cooling. Also, the radiation loss R may be partially compensated by radiation gain from the anode, which must be taken into account.

Evidently our present knowledge and our experimental technique are too limited to permit us to use equation (**21**) for accurate results. It may be used, however, to show orders of magnitude and to set certain upper and lower limits which permit us to draw some important conclusions.

Applications: *Carbon Arc*. Take, for a 10-ampere arc, $V_c = 9.0$ volts, $\varphi_- = 3.9$ volts, $\varphi_+ = 0$, $V_i = 16$ volts. A rough estimate of conductivity loss based on a hot spot area of 0.04 cm.^{2}, temperature gradient 2500 deg. per cm. and conductivity 0.01, gave $C = 0.04$ volt, though the data are uncertain and the writer is inclined to believe that the result is too low. Net loss by radiation, calculated as if cathode and anode hot spots were black body radiators at 3140 deg. $K.$, and 3700 deg. $K.$, respectively, gave $R = 0.75$ volt. E is relatively small, and so is C', provided the arc is not cooled by an air blast. With these values we find

$$f = 0.64, \text{ assuming } F = 0;$$

$$f = 0.63, \text{ assuming } F = 0.25.$$

f could be raised as high as 0.70 by neglecting *all* heat losses, $C + C' + R + E$, which is clearly an upper limit. No reasonable value of φ_+ differing from 0 would produce much change in f. The assumed value of V_c is probably several volts too small, but no reasonable increase would increase f greatly. φ_- could only be given a smaller value if the electrons were pulled out of the cathode by the field, rather than spontaneously emitted thermionically, and we have previously seen that the evidence proves certainly that no *large* effect of this kind can be important in the carbon arc. We thus seem forced from energy considerations to conclude that the fraction of current carried by electrons at the cathode is of the order of 60 to 70 per cent, rather than 99.4 per cent as predicted by Compton's theory. The fact that an earlier calculation[35] appeared to support Compton's theory was due, first, to the use of a value of φ_+ now known to be inadmissible[17] and second, to the use of an impossibly high value for F.

Mercury Arc. In this case, recent experiments by Güntherschulze[14] give apparently accurate data for most of the quantities involved, except for minor corrections pointed out by Seeliger[15] and included here. The data are, in watts (volts) per ampere of arc current, $C = 2.68$; $E = 2.8$ to 3.9, depending on the assumed temperature of the cathode spot; $R = 0.04$. Taking $\varphi_- = 3.9$, $V_i = 10.4$, $\varphi_+ = 0$, $V_c = 8.6$ volts (as a reasonable value owing to the fact that it must lie between lower and upper limits of 5.3 and 10.3 and probably nearer the upper value[14]) knowing C' to be negligible and H zero, and assuming $F = 0$, we find $f = 0.25$ to 0.16. If F is taken to be greater than zero, f becomes still smaller.

Even if cooling by radiation R and evaporation E is entirely neglected, which could only be justified if *all* mercury were lost from the cathode mechanically rather than by evaporation, and even if the cooling φ_- by electron emission were neglected, which would be justified if the emission were due entirely to the "pulling out" effect of the field, still equation (**21**) gives only $f = 0.70$. In any case, therefore, the fraction of current carried by electrons must be less than 70 per cent, whereas Compton's theory predicted 96 per cent.

CONCLUSIONS

From this consideration of energy balance at the cathode, therefore, it would appear that Compton's assumption that the thickness of the cathode fall space is equal to the electron mean free path is incorrect, and that this thickness is much smaller. If it is much smaller, the positive ions must move through it generally without colliding, and we have exactly the space charge condition leading to equation (**20**) of Langmuir's theory. We must therefore consider the evidence as strongly supporting Langmuir's theory.

Further than this, these energy considerations lead us to some conclusions regarding the mechanism of electron emission from the cathode of a mercury arc. Since almost certainly the cathode drop does not exceed the ionizing potential $V_i = 10.4$ volts, it is obvious that no electron can ionize more than once near the cathode. The fraction f cannot, therefore, be less than 0.5 and could only be that small in case the probability of ionization were unity, which cannot be so. From this consideration, f must *exceed* 0.5. An examination of equation (**21**) in connection with Güntherschulze's data shows that a value of $f > 0.5$ can only be obtained if $\varphi_- < 3.9$ and $E < 2.8$ by large margins. In other words, the field at the cathode surface acts to pull out electrons which would not otherwise be liberated, and some of the mercury is lost from the cathode

mechanically, rather than by evaporation. The former of these possibilities was suggested by Langmuir, whose measurements of positive ion current densities led him to estimate the field at the cathode of a mercury arc to be of the order of 10^6 volts per cm. Such fields are known to pull electrons from metal surfaces in the presence of gases or vapors, and would probably be especially effective if the metal surface is heated, as in an arc, so that many electrons need only the additional assistance of the field to permit their escape[45].

CONDITIONS JUST BEYOND THE CATHODE FALL SPACE

This region, generally called the negative glow, is a region in which the concentration of ions is maximum. The electric field is of minimum strength and is often reversed in direction, the current being by diffusion of electrons in the direction of decreasing concentration[39,46]. Probably much of the radiation from this part of the arc is the result of recombination of ions and electrons[47].

CONDITIONS IN THE POSITIVE COLUMN

Here ionization occurs to just a sufficient extent to balance the loss of ions by recombination or diffusion to the walls, if the arc be enclosed. This ionization may be produced thermally, by electron impact, photoelectrically, or by a combination of these. There are reasons for ascribing much of it to high temperature in the carbon arc[35], while this certainly plays no role in the mercury arc, where the ionization is due to electron impacts, probably of a cumulative nature. The light from the positive column is almost certainly due to excitation rather than to recombination[47].

CONDITIONS AT THE ANODE

The anode drop in potential may be positive or negative according to conditions first explained by Langmuir and Mott-Smith[34] as follows: Surrounding the anode is an atmosphere of ions and electrons moving with more or less random motion. If, in this random motion, the excess of electrons over positive ions striking the anode would be greater than the total current in the circuit, then a negative, or reverse, anode drop is set up so as to hold back enough electrons to keep the current to the value demanded by the constants of the circuit. On the other hand, if the number naturally striking the anode is insufficient to carry the current, then a positive anode drop is set up so as to draw in more electrons. From these considerations, it is evident that anode drop decreases with increasing anode area and with increased ion concentration, as can be obtained by using a hollow anode or by promoting ionization near the anode.

The heating of the anode depends on three factors: (1) the heat of condensation of electrons φ_-; (2) the average energy $\overline{V}_-$ of the electrons in their initial random motion; (3) the anode drop V_a, if this be positive. Although this subject has been studied calorimetrically[48] and the order of magnitude of these predictions always verified, thus far only Van Voorhis[42] has measured all the quantities necessary to make an accurate quantitative test, which has exactly verified the above statements. A. W. Hull[49] reports that calorimetric work on high-power mercury arcs at the General Electric laboratory is also in quantitative agreement with these ideas.

From the preceding discussion it will be seen that much progress in the understanding of arc phenomena has been made during the past few years; and that there are at present numerous possibilities for further experimental research, guided by theoretical considerations.

(2) In terms of mechanism, the arc may be defined as a gas discharge in which the ionization near the cathode is produced by electrons which *have* fallen through the cathode fall of potential and thereby gained the energy necessary for ionization, whereas in the glow discharge the ionization is produced while the electrons are falling through the cathode fall space. In the glow discharge the ionization increases exponentially with distance from the cathode: in the arc there is no exponential building up of ionization. This definition is equivalent to the one already given.

(3) Different arc types are sometimes found under conditions in which transitions from one form to another may occur. It is suggested that the primarily "thermionic" arc and the primarily "pulling out of electrons" arc may be two such types. In Table I those arcs whose current densities are thousands of amperes are probably of the latter type and those with smaller current densities of the former type. Both types are shown for tungsten in Table I. There is some evidence of still another arc mechanism (Dr. Slepian, unpublished).

Discussion

Joseph Slepian: There is hardly a scientist on whose work I lean more than Professor Compton's.

I remember as one of the best of Professor Compton's papers the one on the theory of the arc which he gave in the *Physical Review* in 1923, in which he so ably defended the thermionic theory which he has discussed tonight. Today, however, Professor Compton apparently feels that perhaps this theory may not always hold after all.

Remarkable also have been his papers on abnormally low-voltage arcs. The first deals with the theoretical difficulties, almost proving that an arc with a voltage less than the ionizing voltage of the gas is impossible. A later paper, however, demonstrates the existence of arcs with voltage less than the ionizing potential but greater than the resonance potential. Then followed a paper showing that where arcs with voltages lower than the resonance potential had apparently been obtained, oscillations had been present which momentarily would raise the voltage above the resonance potential. Then came still another paper showing that arcs with total voltage less than the resonance potential were possible under suitable conditions.

Another paper which I found exceedingly valuable, stimulating, and instructive, is that one on the Mobility of Ions in Discharges in which he very boldly sets out to calculate the ways in which ions will move in gases of considerable density under the action of the electrical fields, taking account of various kinds of collisions which electrons can have with molecules. This was an exceedingly difficult problem, and I marveled that anyone had the temerity to tackle it. Yet with a few skillful manipulations and ideas, Professor Compton derived equations which are quite easy to understand and exceedingly valuable.

There are some experiences which I have had in connection with my engineering work which I think will be interesting in relation to the theory of the arc. The various theories of the cathode of the arc mentioned by Professor Compton require that a considerable portion of the current be carried by electrons leaving the cathode. The question then arises as to how these electrons get out of the cathode, as ordinarily electrons will not pass from a metal into an adjoining gas. One agency which will assist electrons in escaping from a metal is heat. When its temperature is sufficiently high electrons can pass freely out of a cathode. This is essentially the thermionic theory of the cathode of the arc, which Professor Compton advocated a number of years ago.

Another possibility which Professor Compton has mentioned is that a very high electric gradient may develop at the cathode surface in the arc a gradient so high that the electrons are pulled out of the cathode even though it is not hot enough for thermionic emission.

At the time of the experiments which I am going to describe, I, along with almost everybody else, believed in the thermionic theory of the cathode; that is, that in an arc it was necessary to have a cathode hot enough for thermionic emission. If the cathode was not hot enough for this, an arc discharge would be impossible, and if any discharge was obtained it would have to be a glow or other high-voltage form. I tried to apply these ideas to the development of the arc which follows the breakdown of a spark-gap by application of high voltage.

Since the electrodes of the spark-gap are initially cold, it seemed necessary that the discharge should start as a glow and only after some point of the cathode reached a sufficiently high temperature should the discharge change into an arc. I tried to calculate the time for the heating up of the cathode spot, and therefore the time for the flow to change into an arc, using data for the watts input at the cathode of a glow on copper obtained from other experiments. I found it would take seconds before the copper would get to the melting point, let alone a temperature sufficient for thermionic emission. But the experiment showed that the arc struck almost at once. Immediately after the gap

broke down, the voltage dropped to 20 volts, which is too low for a glow.

I had been of the opinion that the cathode had to be hot in order to maintain an arc; yet here, where the electrodes did not have time to get hot, I was getting a discharge with only 20 volts. More recently, this experiment has been repeated, using the DuFour Oscillograph, and it has been found that the time for the discharge to change from glow to arc is of the order of a microsecond.

Since the cathode couldn't have become hot in so short a time, this experiment made me feel that the thermionic theory of the cathode couldn't be correct; at least not all of the time.

Another experience in connection with my engineering work which made me believe that probably the cathode didn't have to be hot was in studying the operation of switches. I have seen switches in which the arc was blown rapidly along the arcing horns operate, and examined the horns afterward, finding stretches on the arcing horn absolutely free of burning. There might be some oxidation but no evidence of a very high temperature.

This seemed strange and would be hard to explain if the cathode had to be hot enough for thermionic emission. I looked into this a little more closely, and considered the hypothesis that perhaps the arc hopped from point to point, without passing over the intervening stretch, so that this stretch might not appear burned because the arc had not actually played on it.

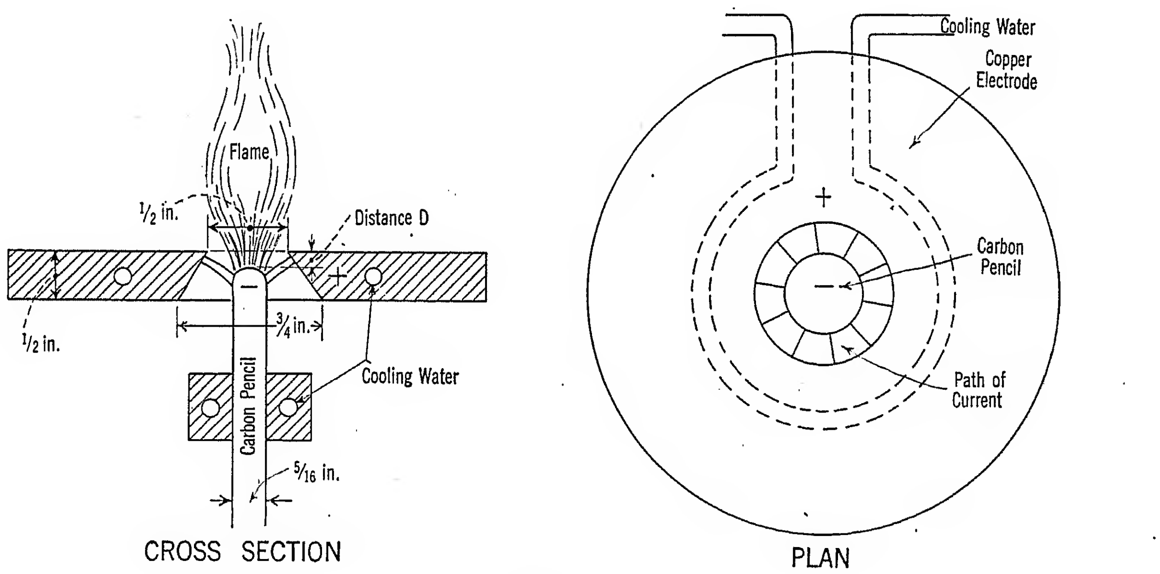

Fig. 1

I eliminated this possibility by bringing the electrodes very close together, and also took photographs with a high-speed camera. I found that even at those spots where the arc had played, as indicated by the photographs, there was no burning.

A German, H. Stolt, has also carried out similar experiments, published in the *Annalen der Physik*. Stolt caused an arc to move over a cathode so rapidly that apparently there was no heating of the cathode. The claims of Stolt were criticized by Güntherschulze, who is mentioned frequently in this paper of Professor Compton's; but Stolt replied quite well to the criticism of Güntherschulze, and I believe that Stolt's conclusions are fairly well established. Stolt did get a low-voltage discharge from copper and other metals, which moved so rapidly over the copper surface that no spot of the copper surface became hot enough to melt, let alone have thermionic emission. This seemed to me to disprove definitely the theory of the necessity for thermionic emission. I have carried experiments similar to Stolt's somewhat further, and have used currents as high as 20,000 amperes; that is, I have moved a 20,000-ampere arc, over a cathode surface so rapidly that there was no melting of the copper but merely a trace of oxidation. Incidentally, the current density in these experiments was of the order of 30,000 amperes per cm.[2]

The application of the method of energy balance at the cathode which Professor Compton has used in his paper for estimating the fraction of the current carried by electrons is certainly very interesting, and the values $f = 0.25$ to $f = 0.16$ obtained for the mercury arc seem significant. If the ionization of the gas next to the cathode is primarily due to collisions from electrons coming from the cathode, f could not be less than 0.50.

Some time ago, I suggested in the *Physical Review* that perhaps no part of the current at the cathode was carried by electrons, but that all of the current was carried by positive ions coming from the highly ionized gas next to the cathode. The cause of the high state of ionization in the gas was to be sought in the very intense energy concentration there. The values of f which Compton finds indicate that this suggestion may be near the truth. Indeed, if a necessary correction to the energy balance equation is applied, the value of f comes even closer to zero in accordance with my suggestion. The correction is as follows. As item (1) under A, "Heating of the Cathode," Professor Compton has "By incoming positive ions, which fall through the cathode drop B_c, $(1 - f)\,(B_c + \phi_+)$." But all the positive ions do not fall through the cathode drop unimpeded. Some will collide with molecules and lose energy to the gas. Also, many positive ions will be reflected from the cathode thus increasing the chances of collision with molecules. Let α be the fraction of the energy acquired by falling through the cathode drop, which a positive ion, on the average gives up to the cathode, Then item (1), under A, becomes $(1 - f)\,(\alpha B_c + \phi_+)$.

Equation (*21*) then becomes

$$f = \frac{\alpha B_c + \phi_+ - F B_i + H - C - C' - R - E}{\alpha B_c + \phi_+ + \phi_- - F\,(B_c B_i)}$$

If we substitute the numerical values used by Compton we get

$$f = \frac{8.6\,\alpha - 5.5}{8.6\,\phi + 3.9} \text{ or } f = \frac{8.6\,\alpha - 6.6}{8.6\,\phi' + 3.9}\,.$$

If we take $\alpha = I$ we get, of course, the values of Compton, $f = 0.25$ and $f = 0.16$. If, however, α is as low as 0.64 by the first formula, or 0.77 by the second formula, we get $f = 0$.

Now what is a reasonable estimate of the value of α? We

may obtain some idea by determining the number of positive ions which cross the cathode space without colliding with a molecule. The electronic mean free path as given by Compton in this paper for the mercury-arc cathode is 4×10^{-5} cm. and therefore the ionic mean free path is 1.0×10^{-5} cm. On the other hand from equation (20) taking $-J = 4000$ as given by Güntherschulze, we find, for d, the cathode-fall space $d = 4.95 \times 10^{-6}$. The fraction of the positive ions which will have free paths greater than the cathode-fall space will therefore be

$$e^{-\frac{4.95 \times 10^{-6}}{1.0 \times 10^{-5}}} = e^{-0.495} = 0.61.$$

That is only 61 per cent of the positive ions crossing the cathode-fall space fail to collide with a gas molecule. Hence a value of α equal to 0.77 does not look altogether unreasonable.

J. C. Lincoln: At the plant of The Lincoln Electric Company, we have run across a new phenomenon which has to do with the nature of the arc and which has changed my notion of what happens in the arc. This phenomenon occurs in a device which we call an "electric torch."

The illustration herewith, shows the arrangement of the parts making up the torch. The copper electrode holder for the negative terminal is water-cooled as well as the copper positive terminal where the path of the cooling water is indicated. The copper anode has a tapered hole of the dimensions indicated on the sketch cut in it. The opening in the anode is round and the dimensions are those of a section through the center of the opening in the anode.

After the parts are set up an arc is started between the carbon cathode and copper anode by short circuiting them with a carbon pencil. While the arc is maintained, a flame projects from the anode as shown in the illustration.

Observation of the arc shows that the size of the flame projecting from the anode is roughly proportional to the amperes across the arc, as might be expected.

Furthermore, with a given current, the flame is larger when the distance D is smaller, the size of the flame decreasing as the distance D is increased.

A change of current causes a much greater difference in the size of the flame than is caused by a proportionate change in the distance D.

The flame is apparently due to very hot carbon particles.

If the flame is cooled, carbon is deposited on the cooling surface just as it would be if the flame from a wick were cooled.

A series of tests was made varying the current and the spacing D. The current was furnished by one of the company's 200-ampere, d-c. welders and was adjusted to 50, 75, 100, and 150 amperes across the arc. The distance D was adjusted to 3/16, 3/8, and 9/16 in. For the results shown in the accompanying table, the flame was above the torch, as shown in the illustration.

To determine the amount of heat in the flame, the amount of cooling water passing through the torch and its rise in temperature were measured. In the tests the initial temperature of the cooling water was 19.1 deg. cent. and 5.375 lb. per minute was used. From these measurements, the heat absorbed by the water was calculated. The rate at which this heat was absorbed was then expressed in watts. It was assumed that the watts input, minus the watts carried off by the water, equals the heat energy in the flame, and the table shows the percentages of heat in the water and the flame respectively.

The results indicate in general that the greater the current, the greater is the energy in the flame; also, that the smaller D is, the greater is the energy in the flame.

The table shows that from $^1/_2$ to $^2/_3$ of the heat appears in the flame, and I believe that if none of the heat developed in the flame was radiated and absorbed by the copper and water, an even larger proportion of the total heat in the arc would appear in the flame.

The direction of the flame can be affected by a magnet. By presenting the south-seeking pole of a bar magnet to the arc, the flame is pushed to one side. So far as I could judge the flame itself is not affected by the magnet. The direction of the flame is a function of the current from the carbon cathode to the anode. To put it another way, the magnet had no effect on the direction of the flame except when close to the arc between the carbon and copper anode.

TABLE I

D in sixteenths of an inch	Amperes	Volts	Watts input	Temp. rise of cooling water, deg. cent.*	Watts absorbed by water	Percentage of heat: In water	Percentage of heat: In flame
3	50	47	2350	5.9	1002	42.5	57.5
6	50	48	2400	6.9	1170	48.8	51.2
3	75	51	3820	8.9	1535	40.2	59.8
6	75	40	3750	9.9	1695	45.2	54.8

9	150	51	7670	23.9	4040	52.7	47.3

*5.375 lb. of water passed per min.

The current between the carbon and copper anode is effected in just the way one would expect from the laws governing electromagnetic action.

When there is no external magnetic field at the arc, the current flows radially between the carbon and the copper anode. When the arc is subjected to an external magnetic field, the current is forced to only a part of the radial path between carbon and copper and at the same time the flame is deflected so that it is more at right angles to the current.

What bearing do these results have on our conception of what takes place in the arc?

The present view is that the voltage across the arc is made up of three portions: (1) the drop at the negative terminal, which must be great enough to heat the terminal to the point where it will throw off ions readily, (2) the I-R drop due to the resistance of the gas stream between anode and cathode, and (3) the drop at the positive terminal which is fixed by the nature of the material and in the carbon arc is much greater than the drop at the negative terminal. The results of the measurements would indicate that in the carbon arc there is a drop at the positive terminal that may be fixed by the nature of the material, but that this drop is not nearly so great as has been supposed. The heat at the positive terminal in the ordinary carbon arc is the sum of the heat due to the inherent drop and the heat of the flame or blast from the negative terminal. The heat due to the flame or blast has been separated largely from the inherent anode drop in the electric torch and measured. The measurements indicate that the heat in the flame or blast is greater on the average than the sum of the anode drop, the cathode drop, and the I-R drop due to the resistance of the gaseous part of the arc.

I do not think it is far from the truth to say that two-thirds of the energy in the carbon arc appear as heat in the flame or blast from the cathode. The question naturally occurs What is the nature of the flame? Two things can be said of it. First, particles of very hot carbon are shot off the end of the cathode and these draw the air with them so that the flame from a match is sucked downward through the opening in the anode when the apparatus is set up so that the flame is below the torch. The current of air was doubtless much stronger when the apparatus was turned over, for it was not possible to get the 9/16-in. reading with 50 amperes, for the arc would not persist long enough to permit of measurement of the heat.

I assumed that this was due to the stronger current of air through the opening in the anode when the apparatus was set up to take the measurements contained in the table.

The second thing is that the actinic value of the flame near the opening in the anode is very much greater than the value in most of the flame. When the flame was focused on the ground glass the image of the flame covered nearly the whole plate, but a short-time photograph showed a very small figure on the plate. The pictures were taken in 1/500 to 1/1000 sec. and at this speed, not more than 10 per cent of the flame that showed on the ground glass plate appeared on the photograph.

A picture of the flame was taken with the camera behind a piece of ½-in. thick pasteboard to see if the active part of the flame contained X-rays. The results were negative.

When the current was reversed in direction, the apparatus refused to work as a torch and the arc apparently tried to run up the carbon when it was made the positive terminal of the arc. This is a most noteworthy fact, for it depends on something beside the electromagnetic forces. In any piece of apparatus with which I am acquainted, the direction of motion is independent of the direction of current, for the reversal of current reverses the flux and with both flux and current reversed, the direction of motion is unchanged.

What is this blast or flame from the cathode? Apparently it is not a stream of electrons, for if it were, it would be affected by a magnetic field. At the same time it must be remembered that approximately two-thirds of the total energy in the arc appears in this flame. It is my opinion that the blast from the cathode in the carbon arc is due to vaporized carbon from the carbon pencil.

We do not know much about the latent heat of carbon, but it is possible and even probable that it is very high. If I am correct in the opinion that most of the energy of the carbon arc is expanded in vaporizing carbon from the carbon cathode and that most of the heat that appears at the positive anode is due to the solidification of the vaporized carbon at the anode, this would be evidence of a large amount of energy required as latent heat to vaporize carbon.

It is my belief that to get a more accurate conception of what occurs in the arc, we shall have to substitute the idea of the blast from the negative terminal as being the central and important thing which occurs in the arc, for the idea that there are inherent anode and cathode drops.

The tests described in this paper show that the flame is a phenomenon associated with the negative terminal.

The old way of looking at it would be to say that the inherent drop at the positive terminal was great enough to produce the heat that actually appears there. This old conception has, I think, been shown to be wrong by these tests.

The old idea was that the current passed across the arc in a solid stream and that a cross-section of the current in the arc would be a circle.

The experiment with the torch, as well as some others not described, indicate that the core of the arc is the blast from the negative terminal and that the current flows outside of the blast and that the section of the current across the arc would be an annulus and not a circle. In such a cross-section, the inner circle would be the cross-section of the blast from the negative terminal and the annulus outside of this inner circle would be the cross section of the current. There is no doubt that this is the true picture of the cross-section of the current in the case of the torch, and I believe it is the true picture in any carbon arc.

P. P. Alexander: I should like to ask Professor Compton to say a few words about the ionizing potentials of different gases. These are well known at ordinary temperatures, but at the temperature of the arc core, apparently, they are entirely different. For instance, the ionizing potential of nitrogen at ordinary temperature is something like 11 volts; at the temperature of the arc core, it appears to be several hundred times less.

I should like to ask Professor Compton if experiments have been made to determine the various ionizing potentials at high temperatures, because knowledge of these potentials is quite essential to the correct interpretation of arc phenomena.

V. Karapetoff: Dr. Compton's paper is mainly concerned with simple, steady arcs, and it is only right that an involved phenomenon should first be studied in its simplest form. In practical applications, we have mostly variable arcs, and our problem is two-fold: (1) To make an arc as steady as possible; for example, in arc furnaces, in electric welding, in arc lamps, rectifiers, etc.; or else, (2) to make an arc as unstable as possible so as to extinguish it quickly; for example, in switches, spark-gaps, relay contacts, flashovers, etc.

In either group of problems, it is of importance to know the factors which contribute both to the stability and instability of an arc, so as to intensify the desirable factors at will. This means that engineers will have to pay more and more attention to the physical nature of the arc, and Dr. Compton's paper, with its references to literature, should prove a valuable introduction to the subject as well as a guide to future investigators.

Dr. Compton quotes several empirical equations for the observed relationship between the voltage and the current in a steady arc. In a transient arc, or spark-over, both the current and the voltage are functions of time, and the apparent total resistance of the arc is variable. Dr. Max Toepler[1] has proposed the following function for this resistance:

$$R_t = k\,F/A_t \qquad \text{(a)}$$

Here k is an empirical constant, F, the length of the arc, and A_t the total quantity of electricity which has passed through the arc from the instant $t = 0$, when it was struck, to the instant t under consideration.

For a transient arc, there is some reason for Toepler's formula, in that the ionized state of the gas is established only gradually, and may be considered a function of the quantity of electricity which has passed through the arc, the conductance increasing with this quantity.

On the other hand, Toepler's formula has some serious defects; namely,

1. The resistance, according to formula (**a**), being infinite at the instant of striking, no finite voltage should be able to start an arc;
2. Should the arc continue over an indefinite period of time, its resistance, according to Toepler, should drop to zero;
3. The ratio of the voltage to the current is assumed to be proportional to the length of the arc; in reality there is a considerable and concentrated fall of potential at the cathode, and some drop at the anode.

It is proposed, therefore, to generalize Toepler's formula as follows:

$$R_t = (k\,F + k^1)/(A_t + q) + r \qquad \textbf{(b)}$$

In this expression, k^1, q, and r are additional constants, introduced for the purpose of correcting the above-mentioned defects of the original formula. When $Q_t = 0$, *i. e.*, at the beginning of the discharge, R_t is no more infinitely large, but has a high finite value, $R_0 = (k\,F + k^1)/q + r$. With a steady arc, when $Q_t = \infty$, the resistance is no more equal to zero, but has the limiting low value of $R_\infty = r$. Furthermore, the resistance is assumed to increase more slowly than the length F of the arc, there being a correction term k^1.

Dr. Otto Mayr has given a general theory of condenser discharge through a resistance and a sphere-gap, using Toepler's formula for the resistance of a transient arc[2]. He has also determined some values of k from the available experimental data. The next step should be to extend his theory on the basis of generalized formula (**b**), and to determine the numerical values of the constants which it contains.

1. *Archiv fur Elek.*, 1925, Vol. 14, p. 306.
2. *Archiv fur Elek.*, 1926, Vol. 17, p. 53.

E. C. Starr: I should like to ask Dr. Compton and the gentlemen who have discussed his paper if they have any data on the order of magnitude of the transient resistance of an arc. I have reference to the type of arc that is initiated by a potential of several thousand volts between electrodes in air at normal pressure and temperature.

The size and shape of the electrodes, as well as the spacing, no doubt affect the resistance considerably. For example, the ionized path between the points of a needle-gap is not uniform in intensity of ionization and the effective cross-sectional area of the path is relatively small compared to the area of the path between large spheres or parallel disks. Hence it is to be expected that the resistance of an arc between the latter type of electrodes should have a lower value throughout the entire period of the transient than in the case of a needle-gap of the same spacing.

Dr. Slepian spoke of measuring the voltage transient of an arc. Perhaps he also recorded the current transient and could therefore readily determine the resistance characteristic.

The transient resistance equation suggested by Prof. Karapetoff should be of considerable value in the calculation of transients in circuits containing spark-gaps if the values of the constants can be determined.

R. W. Sorensen: (communicated after adjournment) I should like to supplement what has been said by telling some of the interesting things relating to arcs that Dr. Millikan and I have found, as we have endeavored to produce a non-arcing switch for use on electric circuits. At California Institute of Technology we have been interrupting high-voltage, high-power electric circuits by means of switches enclosed in a vacuum chamber. To date, we have been very successful in our attempts to do this, largely because the arc at the opening of the switch is very small, and apparently removes a negligible amount of material from the switch terminal when the arc is struck. We have some switches showing practically no burning or pitting of contacts after 4000 operations. Also, by means of relatively small contacts, currents of several thousand amperes at approximately 50,000 volts, have been successfully interrupted. In performing these interruptions, the switch terminals have not been unduly pitted and since there is no pitting of the metal, it is rather difficult to account for the energy dissipation at the switch during the time of opening.

Dr. Compton has defined an arc "as a discharge of electricity between electrodes in a gas or vapor, which has a negative or practically zero volt-ampere characteristic and a voltage drop at the cathodes of the order of the minimum ionizing or minimum exciting potential of the gas or vapor," all of which may be true but we have found from our many experiences that if gas or vapor is required to maintain an arc, the amount required is indeed very small. Perhaps if we could hypothecate a liquid or gas, which will not vaporize at arc temperature, it would still be possible, though it may appear improbable, to start an arc in such a liquid. I should like to ask Dr. Compton how it would affect his definition to leave out the words "gas or vapor" and have his definition read "an arc is a discharge of electricity between electrodes, which has a negative or practically zero volt-ampere characteristic and a voltage drop at the cathode of the minimum ionizing or minimum exciting potential of the material stripped from an electrode at the temperature of the arc." In other words, is it essential that there be a surrounding medium of gas or vapor in order that an arc may be struck by the electrodes.

If for the moment we assume a medium of gas or vapor not essential to the establishment of an arc, we must, of course, look for some other means of explaining the process by which an arc between electrodes is sustained even for a very short period of time. This presents a difficulty, which, however, may not be insurmountable. Contrary to public opinion, the best known vacuum is not a perfect insulator, in the sense that no electric current can be made to pass across such a vacuum, because we now know that electrons can be shot across vacuous spaces. When an arc is struck by the two separating electrodes, there must be present a host of ions or ionized particles, as well as free electrons which serve as the carrier for the arc. Is it not possible to picture a condition under which these carriers may be provided entirely from the electrodes, and not by a surrounding gas?

K. T. Compton: The work to which Dr. Slepian calls attention is, I think, some of the most interesting in connection with the theory of the arc. I made a reference to it in the paper, but I should like to call attention to just one thing for fear of being misunderstood.

There were two theories of Langmuir that have been discussed. One theory has no reference to the origin of the electrons. It would apply independently whether the electrons have thermionic or any other origin. It is merely a space-charge theory.

As to the other theory, *i. e.*, that electrons may be pulled out of the cathode by high electric fields, I think that we have there a possibility of two types of electric arcs. Of course there are often two or even more types of arcs. The character may change from one to the other, but both are recognized as arcs. It seems to me we have brought out in this discussion opportunity at least for two of these.

Dr. Slepian mentioned the case of a copper arc in which the cathode was not melted, and obviously didn't get to the melting temperature. On the other hand, we certainly do have copper arcs in which the copper does melt.

In Table I we notice two tungsten arcs, one with a current density of 3200 amperes per sq. cm., and the other with 700. In the latter case the thermionic emission can be calculated from the temperature that the arc reached. The tungsten melted, and at least reached the melting point of tungsten. In that case (see Table II) the thermionic emission, calculated from the constants of tungsten, comes as near 700 amperes per sq. cm. as the purity of the tungsten would justify. On the other hand, 3200 is clearly too high to be accounted for by thermionic emission. In tungsten we have these two different types, one evidently of thermionic origin and the other of different origin,—perhaps with electrons pulled out (Langmuir) or perhaps arising from intense ionization in front of the cathode (Slepian).

Nottingham used a special type of arc, especially designed to reduce heat conduction so that cathode temperature could rise. He got a large cathode spot. In the case of carbon also we have pretty good evidence of the large proportion of the emission thermionically, and in the case of Pointilite lamps and Tungar rectifiers where we can use a pyrometer to determine the temperature of the various parts of the cathodes, one gets pretty good agreement with the theory of thermionic emission.

In Table I, in the cases where we have current densities running into thousands of amperes per sq. cm. I think, with Dr. Slepian, that thermionic emission is not adequate to account for currents of that order. Another agency must be operative in such cases.

There are two ways in which the temperature may affect the ionizing potential. In the first place, the gas to be ionized may be dissociated from its molecular state into an atomic state as a result of high temperature. That such action is possible has been shown in experimental cases where it is possible to produce this dissociation under conditions that can be controlled, namely, in hydrogen, iodine, etc. In those cases the effect is always to reduce the ionizing potential. This action of temperature is indirect.

As regards any direct effect of temperature on the ionizing potential of the gas, this effect will probably be rather small because translating degrees centigrade into volts, about 8000 deg. cent. correspond to only one volt. There are no laboratory experiments that reach a temperature as high as 8000 deg. So the average energy imparted to electrons as the result of high temperature or to the molecules by high temperature would in general be only a fraction of a volt.

I don't know whether or not there are other ways in which the ionizing potential of the gas might be affected than these. The only ones I know that have been directly investigated have been dissociation of molecular gases into their constituents, and the direct thermal ionization of alkaline vapors in electric furnaces, as done at the Mt. Wilson Observatory.

With regard to the question by Mr. Starr, I am sorry that I cannot give the desired information because I have made no study of transient arc phenomena.

Professor Sorensen's suggestion that the ionization of materials stripped from the electrodes at the temperature of the arc be substituted for that of a surrounding gas or vapor appears to me to be quite permissible as including the interesting discharges which he described as true arcs. In fact such material is included in the term "vapor" in the sense that I have used. The important thing, as I see it, is the presence of some ionizable material in the space between the electrodes.

The great success of this current interrupter seems to be due to the fact that, at such low gas or vapor pressures, the mobility of the ions is so great that they effectively disappear from the arc space during the time of low voltage between voltage reversals. In high-pressure arcs as in oil-immersed circuit breakers, on the other hand, the ion mobility is so small that ions remain in in sufficient concentration to re-strike the arc after the voltage reversal.

In answer to Prof. Karapetoff I wish to say that I never discuss the question of an electric arc with anyone who has had any real practical experience with an electric arc without feeling how limited is the experience which we have in the laboratory. As I said, we physicists work with arcs on a small scale, and the attention of physicists has been devoted to arcs under the simplest conditions in order to find out something about the things going on in the arc. Unfortunately those aren't the arcs met with in engineering practise, where simplicity and even understanding of the phenomena are not the prime considerations. It may be, I am afraid, another generation of physicists which will be able to answer some of the questions which are uppermost in the minds of engineers.

Printing Telegraphs on Non-Loaded Ocean Cables

BY HERBERT ANGEL*

Associate, A. I. E. E.

Synopsis.—*This paper discusses the application of printing telegraphs to ocean cable operation. Reference is made to various improvements in apparatus and operation, tending toward increased output, and the effect of the application of these improvements from the laying of the first cable to the present time. Telegraph codes and their relation to speed and their applicability to printer operation are also discussed.*

Transmission methods, shaping of the signals, variable bias, and the effect of earth currents are also described in the paper. Manual, semi-automatic, and full automatic operation of long ocean cables are covered briefly. The characteristics and advantages of regenerative repeaters are pointed out and the operation of printers on cables described.

* * * * *

HISTORY

SINCE the laying of the first successful ocean cable between Heart's Content, Newfoundland and Valentia, Ireland, cable engineers have worked to increase the output or speed by improving the terminal apparatus and by the use of more efficient operating methods.

The first cables were operated by the manipulation of two keys at the sending terminal of the cable, one used for a dot and the other for a dash of the cable Morse code. At the receiving end these signals were received on the well-known mirror galvanometer. The moving vane of this galvanometer carried a small mirror by means of which a beam of light was projected on a screen and deflected momentarily to the left or right, corresponding to the dot or dash of the Morse code, the center representing a space.

This form of reception was obviously a slow one and was later superseded by Lord Kelvin's siphon recorder. This was a great advance over the former method in that it gave a legible and permanent record of the Morse characters and increased the speed of reception and, therefore, the output of the cable. The next important improvement was the duplexing of the cables permitting simultaneous transmission in each direction which practically doubled the speed of operation.

Further increase in output was obtained by the development of automatic transmitting devices by which a cable could be operated at its maximum signaling speed, another step in advance over the original manual method. Still later came the introduction of magnifiers which so increased the visibility of the received signals that a further increase in the speed of operation was possible. The development of the cable printer permitted a further substantial increase of speed and in addition made the operation entirely automatic.

The progress made in cable operation since the early cables were laid will be more readily appreciated if we note the various steps of increased output of a given cable, laid approximately 50 years ago and which is still in service.

The original speed or output of this type cable when operated with the mirror galvanometer was about 70 letters per minute. By the use of the siphon recorder this speed was increased to 80 letters per minute or 13.3 words per minute. With the application of the duplex principle, by which two messages are sent at the same time, one in each direction, the output was practically doubled to 160 letters per minute. Then followed the introduction of the automatic transmitter raising it to about 220 letters per minute. The addition of the magnifier further increased the output to about 300 letters per minute. With printer operation the output of this cable has been increased to something like 375 letters per minute.

From this review, it will be seen that the original output of this cable of 70 letters per minute has been increased over 500 per cent, all of which has been brought about by the development of transmitting and receiving apparatus.

OBJECT OF PRINTER OPERATION ON OCEAN CABLES

There were at least two objects in view in applying a printing telegraph system to ocean cables, one being to further increase the output of the cable and the other to make the operation wholly automatic.

Up to the time of introduction of the cable printer, cable operation might be considered as semi-automatic, that is, while the transmission was automatic the reception was not, as it was necessary that the siphon recorder signals be manually translated by skilled operators, whereas with printer operation the signals are translated mechanically and printed on a page or tape as may be desired.

PROBLEM OF TRANSMISSION

Before discussing the actual work of the printing system it may be well to consider first the problem of transmission. This being fundamental it should be clearly understood in order to more fully appreciate what follows. In all systems of wire communication a necessary element is the code of signals or telegraphic alphabet to be used for transmitting the message.

*Telegraph Engineer, Western Union Telegraph Co., 195 Broadway, New York, N. Y.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 21-24, 1927.

In this discussion the term *code* may be interpreted as a series of predetermined combinations of one or more electrical impulses or time units. These code combinations must be transmitted over the cable and translated into the letters of the alphabet at the receiving end. The selection of the code, for there are several kinds, determines the number of letters or words per minute which can be transmitted over a cable. The reason for this is that different codes have different time unit lengths. Not only do different codes vary in time unit length, but a particular code may in itself have combinations of variable time unit lengths.

For example, the international Morse code has an average length of about eight and one-half time units per combination or character, some of the combinations containing only four units and some twenty units. In the cable Morse code, which also has combinations of variable length, the average time unit length is 3.7 units. Such codes may be classed as non-uniform codes. Then there are the uniform codes in which each combination is of equal length such as the Baudot code of five time units and the Cook code of three units, so that we have at least four kinds of codes available for transmitting intelligence over the cable.

The next logical step is to determine the best code to use for the work to be undertaken. For this purpose reference will be made to the code used on the cable selected for this comparison and the speed at which the cable is operated. The speed of a cable is usually referred to in terms of the number of letters that can be transmitted and recorded in one minute. This is determined in practise by finding the highest rate of speed or frequency at which alternating current, or as termed in cable practise, reversals of current, can be transmitted over the cable and that will arrive at the receiving end with sufficient amplitude to properly operate or deflect the delicate recording instrument. This rate of speed is termed the working fundamental frequency. It does not, however, mean it to be the maximum frequency of the cable which is probably much greater.

With the code originally used on this particular cable as a basis, it can be determined which code should be used for printer operation, bearing in mind that the printer must necessarily yield an output as good as, or preferably better than the cable Morse code.

Codes

This particular cable was, previous to the installation of the printer, being operated at the rate of 150 letters per minute using the cable Morse code of 3.7 units. This means that the maximum number of time units that can in practise be transmitted over this cable is $150 \times 3.7 = 555$ units, which reduced to terms of fundamental frequency is $\dfrac{555}{60 \times 2}$ or 4.6 cycles per second. The output in letters per minute for any given code is found by dividing the known speed of a given cable in time units per minute, by the figure representing the average number of units of the code under consideration.

Applying this formula to the particular cable just mentioned, the speed of which was 555 time units per minute, the output in letters per minute for the different codes would be:

International (Two-current non-uniform code)	$\dfrac{555}{8.5}$	= 65.3 letters per minute
Cable Morse (Three-current non-uniform code)	$\dfrac{555}{3.7}$	= 150 letters per minute
Baudot (Two-current uniform code)	$\dfrac{555}{5}$	= 111 letters per minute
Cooke (Three-current uniform code)	$\dfrac{555}{3}$	= 185 letters per minute

Of the four codes available for printer operation, it is obvious that the International code gives too low an output and may therefore be eliminated for this reason, and also because a non-uniform code requires a more complex printer mechanism than does a uniform code. The Cable Morse or three-current code may also be eliminated because of its non-uniformity.

This leaves two codes for consideration, the Baudot five-unit and the Cooke three-unit. The five-unit code was chosen for the first experiment.

The question may arise as to why the longer code of the two was selected if increased output is to be a factor in the development of a printing system. The answer is that while both the Baudot five-unit code and the Cooke three-unit code are uniform, so far as their unit lengths are concerned, there is still another important difference. The Baudot is a two-current code while the Cooke is a three-current code. The two-current code is made up of positive and negative impulses and the three-current code of positive, negative, and zero impulses. The two-current code is more desirable for printer operation than the three-current code because it makes for greater simplicity of mechanism.

A further and important reason for selecting the two-current Baudot code of five units is that it is adaptable to a method of transmission, discussed later in the paper, which permits the actual doubling of the number of letters per minute shown in the above table of speeds. In this case we have the apparent paradox of the longer code giving a higher output than the shorter code. The three-current code is not adaptable to this method of transmission.

Notwithstanding these differences, however, both the Baudot and Cooke codes were tried out in actual service for purposes of comparison.

The first cable printer experiment with the five-unit code was tried over an ocean cable previous to the

outbreak of the World War. The results of this experiment were considered satisfactory but a continuation of the test was interrupted due to the war's outbreak and the investigation was then confined to the laboratory. The second ocean cable experiment was tried out in 1916; this was with the three-unit code. The results of this experiment were also considered satisfactory and this system was operated under regular traffic conditions between Ireland and Newfoundland during 1919 and 1920. Later the investigation led back to the five-unit code which was also operated between Ireland and Newfoundland and has been in continuous operation for several years.

Principle of Ocean Cable Printing Telegraph System

A printing telegraph system applied to an ocean cable does not necessarily introduce new features with respect to the actual operation of the cable itself. It merely provides an organization of apparatus for transmitting the signals representing the letters of the alphabet and for causing them to be automatically translated into printed characters at the receiving end of the cable. Heretofore, this translation has been the work of the skilled operator.

Basis of the System

The basis of the cable printing telegraph system is a selective sending and receiving apparatus synchronously operated.

The sending apparatus includes a perforating machine resembling a typewriter keyboard which is used by the operator for preparing the message on a strip of paper tape, a constant-speed distributor or transmitter, driven by a tuning or driving fork, combined so as to select and transmit in proper sequence the code or letter combinations set up in the strip of tape.

The receiving apparatus includes a constant-speed distributor, also driven by a fork, and an automatic typewriter or printer, combined to select automatically the received signals or letters and cause them to operate the type bars of the automatic printer.

In Figure 1 is shown schematically a single channel printing system. In the transmitter at the upper left of the figure, T is the perforated strip of tape which feeds continuously through the transmitter at a constant speed.

The five reciprocating pins or rods $U\ P$ of the transmitter are operated seriatem by the five cams on the cam shaft $C\ S$. When a pin finds a hole in the tape it rises through the tape and rocks the pole-changer $P\ C$ to its marking contact $M\ C$. The absence of a hole causes it to be rocked to its spacing contact $S\ C$. The pins $U\ P$ which rise one after another are slightly staggered to compensate for the moving tape. The pole-changer operates a transmitting relay A, through circuit $C\ T$, which in turn operates the regular cable sending-on relays B that transmit into the cable through the sending condenser K. At the receiving end of the cable in the cross circuit of the duplex bridge are located the magnifier and cable relay. These instruments are comparatively sensitive to small currents, the magnifier requiring only five or six microamperes to operate it and the relay something in the order of 50 to 80 microamperes to give a good working signal. The contacts of the relay are shown connected to two local relays C which operate into the printer circuit.

From here the circuit extends through $C\ X$ and $C\ W$ into the two control relays $C\ R^1$ and $C\ R^2$ and the printer relay $P\ R$ of the printer circuit, returning to the battery source at $C\ Z$.

The two control relays $C\ R^1$, $C\ R^2$ control the fork through magnet F^1 and keep it vibrating in synchronism and in phase with the distant transmitter. The driving fork in turn operates a step-by-step distributor through its contacts $F\ T^1$ and $F\ M^1$ and the distributor magnet. The magnet rotates a cam shaft containing a series of cams, C, which raise the levers $A1$ to $A6$ in sequence. These in turn close the selecting contacts 1 to 5 of the printer selecting magnets.

This arrangement of sending and receiving apparatus, operating synchronously, causes the five selecting contacts of the receiving apparatus to function in step with the five reciprocating pins of the transmitter, so that an impulse transmitted through the medium of any one pin of the transmitter will be received on the corresponding selecting contact of the receiving distributor. Mounted on the shaft with the five cams referred to is a sixth cam, the purpose of which is to cause the printer to function after the five selecting cams have completed their cycle.

To illustrate the actual transmission and reception of a signal the letter O, which we may assume has been prepared on the tape by the operator, will be followed through the transmitter. If we keep in mind the fact that the transmitter and receiving distributor are running in exact step, it will be quite simple to follow the train of events which occur to bring about the printing of any given character. We will assume that the tape is being fed into the transmitter and that the holes for the letter O are just passing over the transmitter pins. In this case the fourth and fifth pins become operative and rock the pole-changer to its marking contact $M\ C$ for a two-unit time length. The marking sending-on relay then operates and transmits negative or selecting current to the cable which in turn deflects the magnifier at the receiving end and correspondingly the cable relay to its marking contact for two units of time.

In this case the local marking relay, the control relay $C\ R^1$ and printer relay $P\ R$ are operated by the cable relay and therefore move their tongues to their marking contacts M. The control relay $C\ R^2$ moves its tongue to its spacing contact because its winding is in opposite direction to that of relay $C\ R^1$. Neglecting the operation of the intermediate control relays we pass on to the printer relay $P\ R$ which as stated was operated to its marking contact by the cable relay. From here the

current path is through the selecting contacts 4 and 5 of the distributor, which correspondingly closed in step with the pins of the transmitter, causing the operation of selecting magnets 4 and 5 of the printer which control the *O* type bar.

The current which operates the selecting magnets has its source from the middle point of the potentiometer $R^1 R^2$, condenser K^1 fork tine *F* and contact *F M* (when closed), resistance $R\,S^2$, tongue *T* of printer relay *P R*, contact *M*, resistance *R S*, to the common connection of the upper distributor contacts *C C*, thence through the corresponding lower springs of the fourth and fifth selecting contacts to their associated printer selector magnets 4 and 5.

While the above description discloses in simple form the operation of a one-channel printer system as applied to ocean cables, it does not attempt to describe the operation in its entirety.

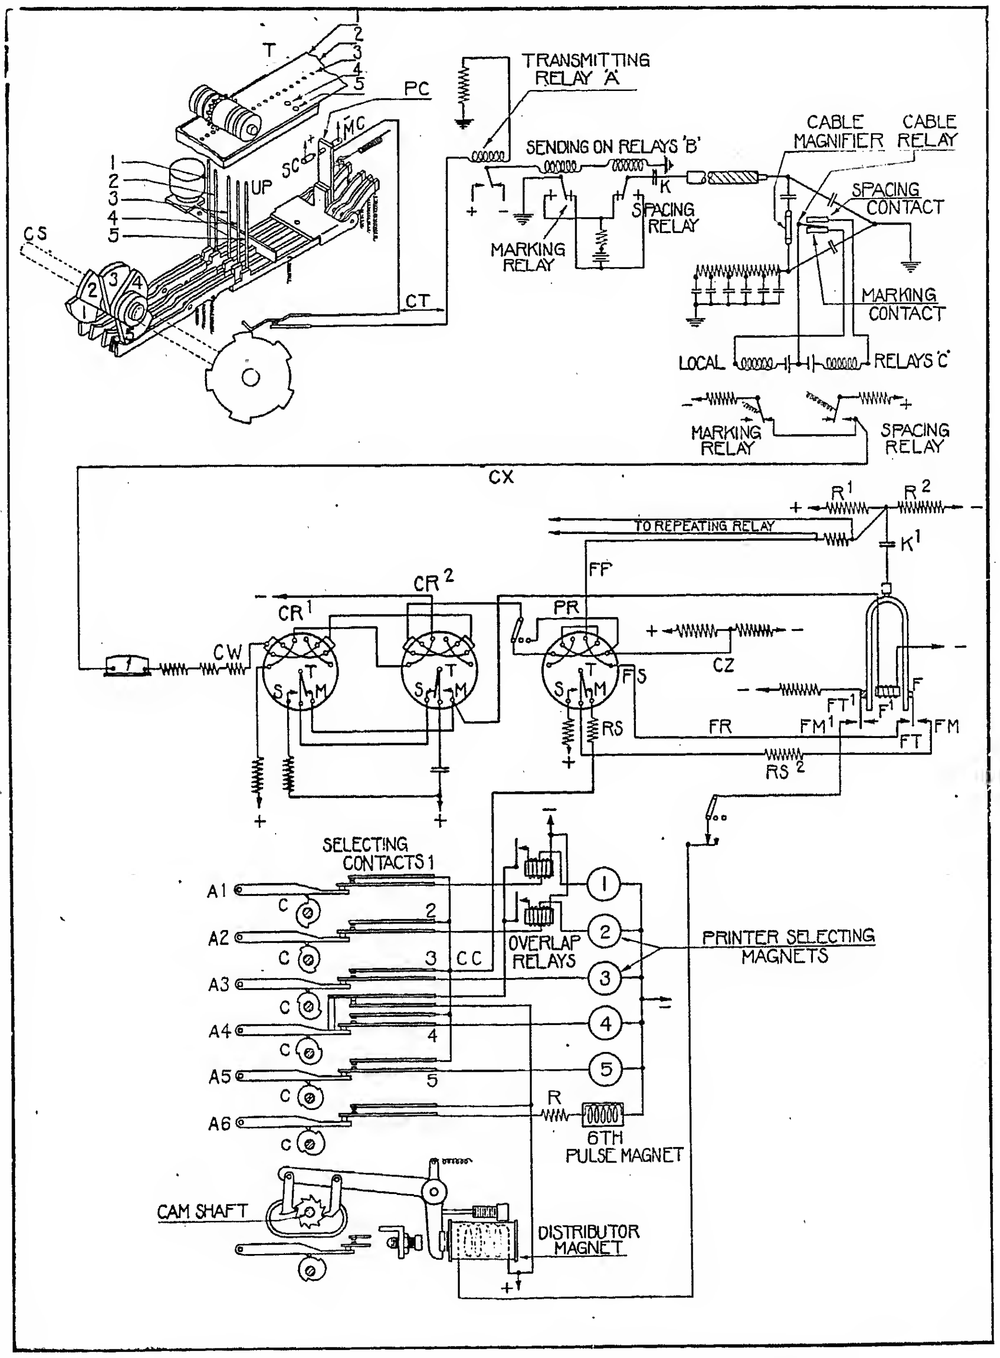

Fig. 1—Schematic Diagram of Cable Printer Circuits

There are at least two features in connection with this cable printing system which may be considered as outstanding, to which reference should be made.

One feature is the relatively low fundamental line frequency required for a given output in words per minute as compared with so-called five-unit single

channel printing systems used in land line operation. The reason for this is what may be called "continuous transmission," that is, the five code impulses of the cable printing system are transmitted successively without any additional intervening impulses being sent between the fifth and first impulse. Up to the time that the cable printer was developed, the land line single channel systems transmitted seven impulses per revolution of the distributor. This lengthened the code to seven time units, five units being used for the code and two units for synchronizing and overlapping time

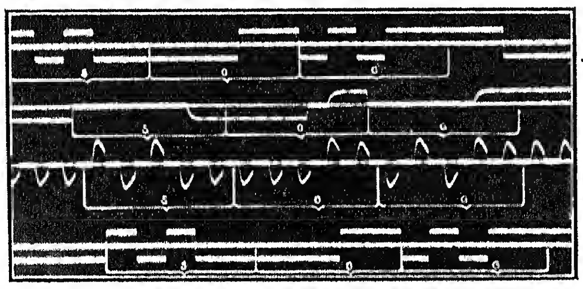

Fig. 2—Oscillogram of Cable Printer Signals

between the fifth and first impulses. The difference between 5 and 7 units gives the cable printing system about 1.5 times more letters at any given frequency.

The other feature was earlier referred to in this paper as a method of transmission by which it becomes possible to double the output of a five-unit code printer system. That is to say the five-unit code is made to yield an output better than the shorter cable Morse code. This is brought about in the following manner:

Referring to the paragraph under Codes, it was shown that the practical fundamental frequency of the cable in question was 4.6 cycles per sec. or 555 half waves per min. Also that these waves or signals in cable Morse operation must be of sufficient amplitude to properly operate the delicate cable relay. Further it was shown that at the above frequency the cable Morse yielded 150 letters per minute and the five-unit code 111 letters per minute.

Heretofore, in cable work, it has been the practise only to increase the speed of transmission to such a point that the attenuation of the arrival signals does not decrease the amplitude below that required to properly operate the delicate receiving relay. In this method of transmission when applying printer operation to long cables, increased speed is brought about by taking advantage of the attenuation.[2]

This is accomplished by increasing the rate of transmission to practically twice the rate of the cable Morse speed. In this case the fundamental waves or alternations are attenuated to such an extent that they are practically undiscernable at the receiving end of the cable and, of course, cease to deflect the cable relay. To all intents and purposes these waves arrive as zero impulses similar to zero impulses as employed in cable Morse code operation. A wave of two-unit length, however, will now arrive with the same amplitude and duration as a single wave in cable Morse operation.

It will be understood from this then that a single wave or a series of alternating waves will arrive at the distant end of the cable as zero waves and that the cable relay will now be deflected only by a wave two or more units in length. In the case of the non-arrival of the single waves, a local impulse or wave producer is employed to fill in the missing impulses and to reconstruct or regenerate the received signals so that they resemble the original transmitted signal.[3]

This wave producer forms a part of the printer regenerative circuit. It is shown theoretically in Fig. 1 at F, $F\ T$, $F\ R$, $F\ S$, and $F\ P$ to potentiometer $R^1\ R^2$. This circuit is through an auxiliary winding of the printer relay which reverses the relay tongue to its opposite contact when the cable relay is deflected to the no-mans-land or zero position and automatically fills in locally the reversal waves which fail to arrive.

The transmitted, received, and regenerated signals are shown in Fig. 2 in which are depicted the combinations of impulses or waves for the characters $S\ O\ G$.

A = the signals from the contacts of the transmitter.

B = the signals from the contacts of the cable local relays showing a straight zero line where the single waves are missing.

C = the signals from the cable local relays (B signals) picked off by the regenerating action of the printer apparatus and the missing impulses filled in.

D = the B and C signals reassembled and regenerated into their original shape as at A.

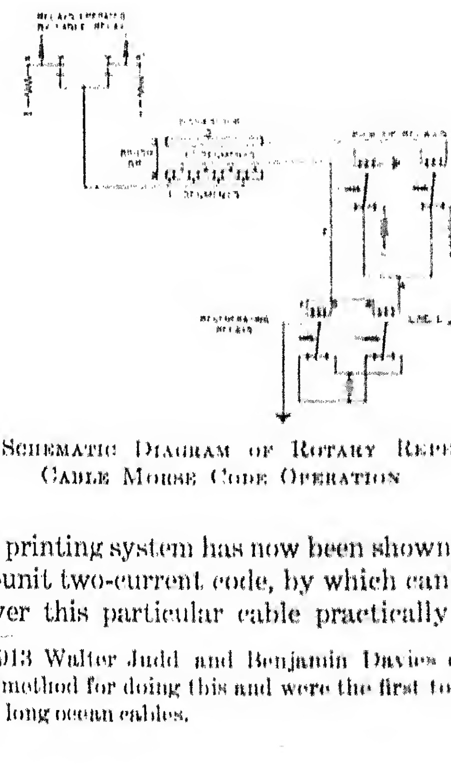

Fig. 2A—Schematic Diagram of Rotary Repeater for Cable Morse Code Operation

A cable printing system has now been shown, employing a five-unit two-current code, by which can be transmitted over this particular cable practically twice as

2. This principle was first suggested by K. Gulstad in 1898, and was applied to the operation of comparatively short sections of cable.

3. In 1913 Walter Judd and Benjamin Davies of England invented a method for doing this and were the first to apply this principle to long ocean cables.

many impulses as can be sent with the three-current cable Morse system; namely, 555 × 2 or 1110 impulses per minute. Correspondingly a greater number of letters per minute are transmitted *viz.* $\frac{1110}{5}$ or 222 letters, as compared with 150 letters obtained with the cable Morse code.

The Cooke three-current code and the cable Morse three-current code cannot be used in the manner just described because a zero current element forms part of these codes. Hence, there would be no way to differentiate between the zero forming part of the code and the zero resulting from the suppression of the single waves.

As already stated in the earlier part of this paper, the printing system was successfully operated over an ocean cable between Ireland and Newfoundland. This was not, however, the final solution of printer application to ocean cables. The next problem was to extend the system so that it would operate directly between the two terminals of a cable circuit, as between London and New York. In connection with this particular phase of the undertaking, we will revert for a moment to a brief history of the prevailing practise in cable operation between the terminal offices.

Fig. 3 is an outline of a cable circuit extending from London to New York or beyond. Up to about the time that the cable printer was conceived, practically all cable circuits were operated sectionally. For instance, in the case of a message whose destination was New York, London transmitted the message to Valentia, Ireland, through the repeating offices at Bristol and Penzance. The operators at Valentia translated the message and re-sent it to Heart's Content, Newfoundland: here the message was again translated and re-sent to North Sydney, Canada, where it was once more translated and resent to New York through the repeating offices at St. John, Canada, and Boston. Under these conditions the overall time consumed in passing messages between London and New York, or vice versa, was in some cases excessive. It is fair to state, however, that under certain conditions messages were regularly exchanged between these two telegraph centers within a minute. It is quite obvious that a semi-automatic system such as this could not be expected to meet the requirements of the ever increasing volume of traffic passing between Europe and America. The ultimate system must be wholly automatic, requiring no manual translation or retransmission between any two terminals of a long cable circuit. This problem was met, and the solution provided, by the development of the regenerative repeater. A regenerative repeater consists of apparatus which to all intents and purposes functions similarly to the printing system which we have just discussed.

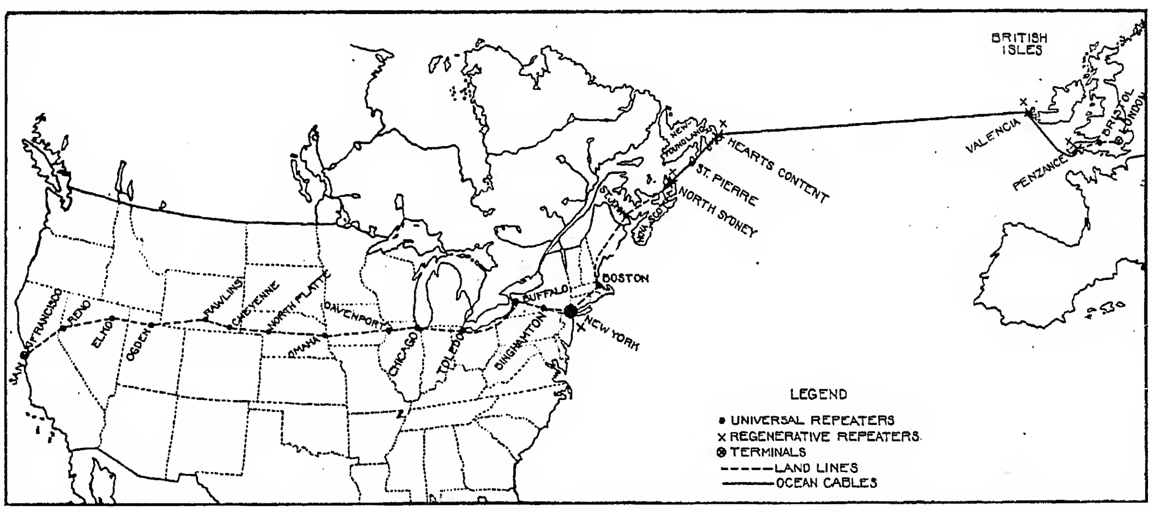

Fig. 3—Map of London—San Francisco Circuit

It must be capable of mending, as it were, or reconstructing the more or less distorted signals received at the end of a land line or cable and retransmitting them into the next section, as new or regenerated signals. Distortion of signals is due to various causes, such as unbalanced duplex conditions, earth currents, characteristic cable effects, and other extraneous disturbances. Without the regenerative repeater it would be almost impossible to satisfactorily operate a long cable circuit.

There are at least two kinds of regenerative repeaters, one known as the rotary and the other as the fork repeater. These repeaters are arranged to repeat any of the codes which may be used in telegraph operation. Such a repeater consists of synchronous apparatus arranged to pick out the best portion of the arrival signal and reconstruct it so that it is identical with its original shape. Fig. 2 illustrates the progression of the operation of the repeater, the progression being in the order of B, C, D.

B = the received signals from the cable local relay contacts.

C = the picking out and filling in process.

D = the reconstructed signals to be transmitted into the next section.

This type of repeater permits direct operation between terminals separated by great distances. As an example of its efficiency, a direct circuit with printer operation was successfully worked between London and San Francisco. This circuit was about 7400 mi. in length including 2600 mi. of submarine cable and 4800 mi. of open line. There were twenty-one repeaters in the circuit, five being regenerators between New York and London and the remainder being standard land line repeaters. The occasion for this circuit was the Diamond Jubilee of the Birthday of San Francisco, September 5, 1925. As part of the program London and San Francisco exchanged greetings and other messages, while London had the honor of starting the grand march in the ballroom of the Civic Auditorium by transmitting signals which operated the bell signal in the printer at San Francisco. The mechanism of the printer was arranged to control at a remote point, the hammer of a huge bell borrowed from one of the San Francisco ferry boats.

These signals transmitted by London were synchronized with the strokes of "Big Ben" which chimed at 7:00 a. m. London daylight time, equivalent to 10:00 p. m. standard time at San Francisco. The printed characters as received on the printer in San Francisco were projected on a large screen so that the exchange of greetings could be seen and read by the vast audience. Fig. 3 shows the magnitude of the London-San Francisco circuit. We might say here that this circuit worked perfectly in duplex operation and messages were sent and acknowledged in one minute.

Regenerative Repeaters

Regenerative repeaters have been in use on the Western Union cable circuits for a number of years and practically all of its old type ocean cables are operated as direct through circuits between London and New York.

As before stated the repeaters are arranged to handle any of the telegraph codes which may be used. Some repeat the non-uniform cable code, others the straight uniform two-current code, and others the modified uniform two-current code. In some cases many of the signals arriving at the end of a circuit, whether it be cable or land line, are so distorted as to be unintelligible for sight reading to the skilled operator, yet the repeater through the medium of its regenerative action will neglect the bad portions of the signal and pick out enough of the good portion to reconstruct a whole new signal.

In addition to the type of regenerator disclosed in Fig. 1 in connection with the printer, another type of regenerator is shown in Fig. 2A. Here the regenerator is shown as adapted for cable code. The segments *C* pick up a portion of the received signal from the relays *R* and R^1 and transmit it into the biased pick-up relays via brush *B R* and ring *S*. These relays in turn operate the biased regenerating relays via *A*, *B*, *C*, *D*, *E*, segments C^1, ring *S* and the windings of the pick-up relays. The regenerative relays transmit the new signal into line *L*.

Reception of Signals Over Ocean Cables

The quality or definition of the received signals has such a direct bearing on the operation of printing telegraphs over ocean cables that it necessarily becomes of primary importance. Much has been written about this particular subject and cable engineers have devoted considerable time towards improving the definition of cable signals. The recent new type of permalloy loaded cable developed by the Western Electric Company is a radical departure in cable design and has considerably increased the cable output above that of the best cables of the standard type.

Reception of cable signals in its final analysis simmers down to "signal shape," for there is a great difference between the sent and received signals, the latter arriving with a non-uniformity of shape which must be

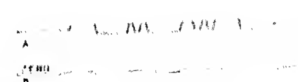

Fig. 4 Showing Difference Between Sent and Received Signals

corrected to produce the best results. The cause for the non-permanent condition at the end of the cable is due in some measure to the characteristic effects of the cable itself and their relation to the delicate receiving apparatus which it becomes necessary to use. If the receiving instrument be a siphon recorder, these effects are not so detrimental, but for automatic or printer operation in which a cable relay is required, they must be counteracted so as to produce signals in order to function automatic apparatus.

As an illustration of the relative difference between the shape of the transmitted and received signals, a group of signals is shown in Fig. 4, in which *A* equals the transmitted signals recorded from the contacts of the transmitter and *B* the received signals traced by the siphon recorder. It is this difference between the sent and received signals which must be corrected for automatic working.

In the discussion of the reception of cable signals, at least four characteristic effects met with in every day working are referred to, namely:

1. The "swaying effect" caused by earth currents.
2. The "falling away effect" of certain signals due to the charging up process of the cable and its associated condensers.
3. The "wandering zero effect."
4. The "variable lag effect."

The latter two effects are the result of a condition in the cable brought about by the transmission of impulses having variable lengths.

To illustrate the means for counteracting these different effects, a schematic diagram of a cable circuit as used for printer operation is represented in Fig. 5. In the figure, M is the magnifier and $C R$ the cable relay.[4] Different types of magnifiers are used in cable operation but reference will be made to the magnifier used in connection with the printer experiments. This is known as the Heurtley hot wire magnifier. It has a moving coil to which is attached a pointer, the movement of the pointer functioning to unbalance the arms of a local Wheatstone bridge circuit. The insert in Fig. 5 shows, theoretically, this type of magnifier.

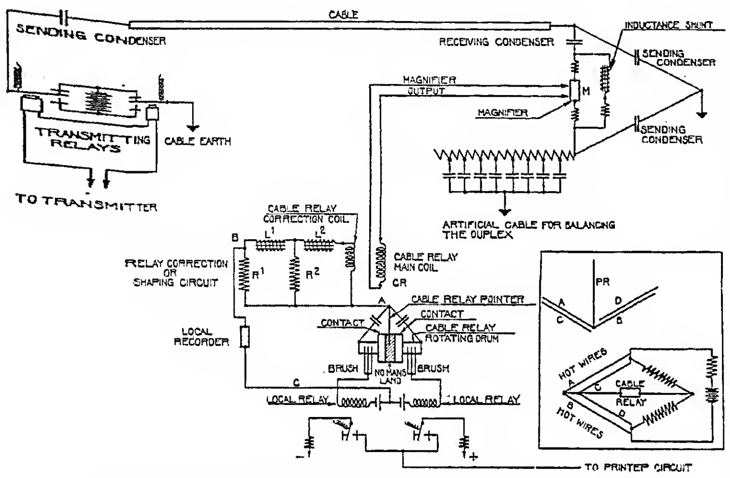

Fig. 5—Schematic Diagram of Cable Circuit

The pointer $P R$ moves the two wires A, B so that A approaches a fixed wire C, while B recedes from a fixed wire D and vice versa. The four wires are heated with the local current in the bridge circuit and connected to form arms of the Wheatstone bridge. As the wire A approaches C, it is subjected to a greater amount of heat and B to a lesser amount; correspondingly the resistance of the wires change and unbalance the bridge. The output of the magnifier is taken from the cross wire of the bridge circuit.

In the figure it is shown that the cable is operated with unshunted sending and receiving condensers. The receiving end shows duplex connections, the sending end being shown in simplex for simplicity. The condensers serve the purpose of preventing to a certain extent the flow of the relatively low-frequency earth currents which are more or less prevalent in transatlantic cables. In some cases, however, earth currents reach considerable magnitude and may change or fluctuate so rapidly as to interfere with the operation of the cable.

4. There are at least three types of cable relays; the Drum relay of S. G. Brown, England, Gold Wire Relay of A. Muirhead, England, Antenna Relay of Eastern Telegraph Company, England.

The inductance shunt in Fig. 5 serves a two-fold purpose. It helps to improve the definition of the received signal and to counteract the effect of "wandering zero." Its action on the received signal is such that it offers a comparatively high impedance to the beginning of a signal, allowing the major portion of the received current to flow through the magnifier coil, then as the signal gradually falls away, the low ohmic resistance of the shunt comes into action and shunts the current from the magnifier coil, producing a signal with well defined slopes. The low ohmic resistance of the shunt also serves the purpose of a bypass for all low-frequency currents and within certain limits counteracts the effect of "wandering zero." The correction or shaping circuit in Fig. 5 is for counteracting the "falling away effect" of the arrival signals as they are passed into the cable relay and for transforming the curved waves into square topped signals.[5]

In Fig. 6 is shown a group of signals in which A represents the original transmitted signals recorded from the transmitter contacts which it is desired to reproduce at the distant end. B represents the received signals as they pass into the cable relay from the magnifier. For the purpose of illustrating the "wandering zero effect" and the "falling away effect" upon these signals, a zero line has been drawn through the curves to show how the zero portions of the curves have wandered from true zero at X, X^1.

Record C shows the signals from the contacts of the cable local relays before the correction has been applied. Record D shows the signals with the correction circuit applied and illustrates how it has held up the current waves and straightened out the zero waves.

The correction shown at D was brought about by applying a local current to the correction winding of the cable relay coil at a suitable moment when the signals began to fall away. This correction winding is shown

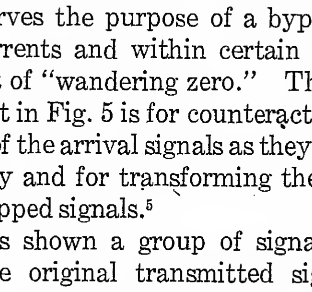

Fig. 6—Showing Uncorrected and Corrected Signals

in Fig. 5. The local current in this winding is regulated by the resistances R^1 R^2 in the shaping network and is timed by the inductances L^1, L^2 to take hold, as it were, at the proper moment. Actually what happens is this: The relay pointer, for instance, is deflected to a contact presumably to record a wave of several units in length, say, any one of the current waves shown in record B, Fig. 6. At some moment during the charging

5. This method of signal shaping was invented by S. G. Brown of England.

process of the cable and condensers the current wave Z begins to fall away and eventually the slope of the wave drifts over to the opposite side of zero as at Q in Fig. 6.

The local correction circuit comes into action at the moment the pointer touches its contact at which time a local circuit is formed through the correction coil via the network, A, B, C, Fig. 5. Through the medium of the slow time constant of these inductances a minute current flows and gradually increases in strength in opposite direction to the falling signal and automatically counteracts the gradual "falling away effect" and holds the signal up for its full length as illustrated in record D. In the case of printer operation these signals shown at D are in turn regenerated by means of the regenerative feature of the printer apparatus in which case the single unit impulses arriving as zero waves are filled in and reconstructed to their original shape as shown at A.

Variable Lag

Variable lag is only troublesome in connection with the reception of cable signals in their relation to synchronous automatic operation. In ordinary siphon recorder operation it is not apparent. Its effect is to shift or displace the arrived signal so that it does not arrive in the exact location assigned to it on the receiving distributor. That is to say, the synchronous receiving distributor, the face plate of which is cut into equal receiving segments, assumes the successive impulses or waves of each code combination will arrive so that a definite portion of each wave will fall upon a definite point on the distributor. As a matter of fact

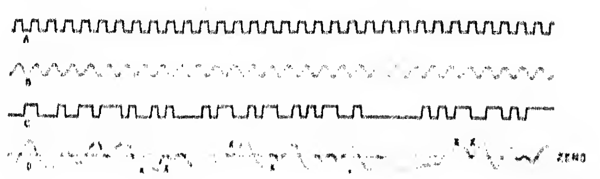

Fig. 7 Showing Signals of Equal and Unequal Length

this is not the case and in extreme cases it has been found that the signals are displaced about 35 per cent of their unit length.

Methods for Counteracting the Effect of Variable Lag

Variable lag is the result of irregular or non-uniform transmission. A regular or uniform transmission is one in which continuous alternations or reversals of current of equal amplitude and duration are sent into the cable, and if the alternate half waves be free from bias or other defects the electrical condition of the cable remains constant and the waves arrive in exact phase with the corresponding segments of the receiving distributor. Any deviation from this kind of transmission produces a variable condition in the cable and the effects of shifting lag become evident, resulting in the wave crests appearing at indefinite points on the receiving distributor.

The difference between arrival signals com alternating or equal length signals and unequ signals, is shown in the groups of signals in which A and B represent the sent and receiv nating or equal length signals and C and D the received signals of unequal length. For this ill the shaping circuits in the cross-circuit of th bridge were disconnected in order to recor unshaped signals for the purpose of portrayi clearly the action of the cable upon these two transmission. It is obvious that the unequ signals arrive in a somewhat disorderly sha dicated in D at X, where some of the waves h to cross the zero line and others failed to r zero line.

To counteract or correct the shifting effect signals, several methods are employed. One used in all synchronous telegraph systems is t the length of the receiving segments with resp sending segments. In general practise this care of any shifting up to 50 per cent of

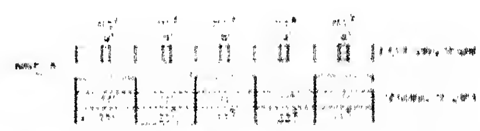

Fig. 8 Theoretical Diagram Showing the Re of the Receiving Segments with Respect to t mitted Wave

unit length. In addition to this the receiving tor is arranged so that the segments can be ro suitable position to compensate for the avera of shifting which may be encountered. To this method of lag correction, two developed d rings are shown in Fig. 8. In this case a sin mitted time unit or half wave occupies a se 72 degrees of the sending distributor face plat shown cut into five equal segments. From it is obvious that on account of the receiving being shortened, which in this case are one-t length of the sending segments, the wave A forwards or backwards approximately 50 per length before it will encroach upon the rece ments $R\,S^3$ or $R\,S^1$. Such an amount of s abnormal and is rarely met with in every day All the lesser degrees of shifting occur within zones and are less harmful. While this count effect of the variable lag, it does not elimina must be dealt with at the transmission end of t

With this in mind there have been devise ways for transmitting cable signals, the obje approach as nearly as possible an alternati form of transmission. For practical purpo not yet been possible to transmit telegraph used for ocean cable operation in the form of alternating waves. A modification of this transmission was developed, however, kno

"suppressed transmission," whereby the code characters are transmitted in the form of broken alternating waves or reversals.

This is by far the best form of cable transmission yet presented and keeps the cable in an even state and counteracts or reduces as far as possible the variable lag. It was developed during the early stages of the printer experiments, and some outstanding results were obtained with it. It is not being used at present on account of its apparent limitations as to speed of operation. Further investigations, however, are being made with it because by taking into account its simplified receiving circuit and the fact that the duplex balancing of the cable is made easier as compared with other forms of transmission, it may be possible to increase the magnification, at present limited on account of cable unbalance, so that the suppressed transmission might be worked up to a relatively high rate of speed.

Operation of Suppressed Transmission—Earthing Method

In Fig. 9 is shown a schematic diagram of one of several methods used for this kind of transmission. The transmitting circuit is arranged so that if two or any greater number of unit impulses of like polarity

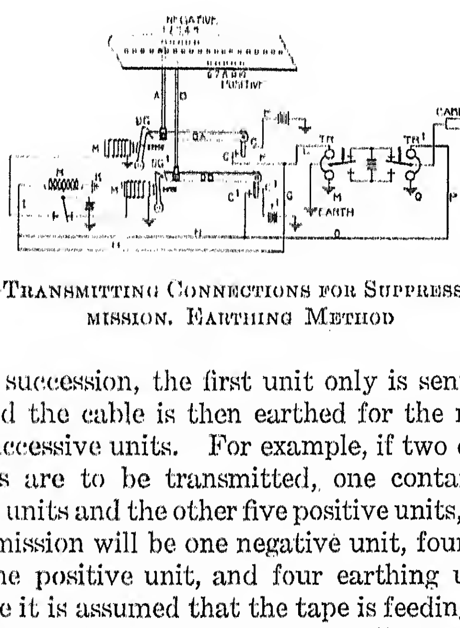

Fig. 9—Transmitting Connections for Suppressed Transmission. Earthing Method

come in succession, the first unit only is sent into the cable and the cable is then earthed for the remainder of the successive units. For example, if two code combinations are to be transmitted, one containing five negative units and the other five positive units, the order of transmission will be one negative unit, four earthing units, one positive unit, and four earthing units. In the figure it is assumed that the tape is feeding towards the left until hole 1 is presented to oscillating pin A.

As pin A rises through the tape, contacts C, C are closed energizing relay R via E, C, C, F, G, H, I, R, K, in a right direction. The closing of contacts C, C causes the latch magnet M to be deenergized through the contacts of relay R. This causes the latch $D\,G$ of latch magnet M to fall into the path of the oscillating lever $O\,A$ connected to pin A. As oscillating pin A is withdrawn from the hole number 1, it is prevented from further rising by the engagement of the oscillating lever $O\,A$ with the latch $D\,G$ as shown.

At the moment contacts, C, C closed, transmitting relay $T\,R$ closed via E, C, C, F, L, M and transmitted one time unit of negative current to the cable, then when contacts C, C opened, transmitting relay $T\,R$ returned to its upper contact and earthed the cable for the remaining units, 2, 3, 4, 5. The action of oscillating pin B is identically the same as that of A; in this case, however, one positive unit is transmitted by transmitting relay $T\,R^1$ via F^1, C^1, C^1, O, P, Q and the cable earthed for the remaining units 7, 8, 9, 10.

Fig. 10 illustrates the suppressed earthing method of transmission in which A represents signals transmitted as blocks and B the signals with all but the first unit suppressed and the cable earthed during the time of suppression. While this kind of transmission greatly reduces the cause of variable lag, some lag still exists, for as already stated the cable can only be kept in an even electrical state when continuous or unbroken alternating current waves are transmitted, whereas in this case the alternate waves are transmitted in a non-continuous or broken form separated by variable length zero or earthing waves which still displace the signals to some extent.

The results obtained at the receiving end of the cable with this kind of transmission are really outstanding. The received signals being in the form of alternate current waves of unit length, arrive with extremely clear definition requiring the simplest form of shaping circuit. An important feature regarding the operation of a cable circuit with this kind of transmission, which will be appreciated by cable engineers, is the relatively small amount of time required to get the circuit going. At cable stations it is not uncommon when starting up a new cable circuit to spend one or more days adjusting the shape of the variable length cable signals, whereas with the suppressed transmission the shaping can be accomplished in a few minutes.

As an example of this we may refer to the first trial or experiment made with the "suppressed transmission" over an actual cable circuit. This cable was about 1400 nautical miles long having a total resistance of 4200 ohms and a total capacity of 476 microfarads. The time consumed in getting working results was well within an hour, which, in the opinion of cable engineers, is a very good performance. This included setting the terminal transmitting apparatus at a suitable speed for operating this particular cable, adjusting or shaping the signals at the other end of the cable, and repeating the signals, without the aid of a regenerator, back over the same cable to the terminal station where they were again reshaped and turned into the printer apparatus. It is fair to add that the attendants at the cable station had no previous experience in shaping this type of signal.

Suppressed Transmission-Insulating Method

Another form of transmission tried out to counteract the variable lag effect is a "suppressed transmission" in which the cable is insulated instead of being earthed[6],

6. First tried by Mr. Pierre Picard in 1898.

all else remaining the same as in the other method. Considerable time was devoted to this method of working and trials were made over one of the long Atlantic cables for a period of several months. It was found that the characteristic effects of the cable using the circuit arrangement shown in Fig. 5 were just as dominant with this kind of transmission as with the standard method.

Fig. 11 depicts a simplified form of the transmitting circuit used for this kind of transmission. In the figure

Fig. 10—Showing Difference Between Standard and Suppressed Transmission. Earthing Method

K represents a key which may be the contacts of a transmitter. Depressing K operates relay R^1 and raising K operates relay R^2. The condenser C is adjusted to hold either relay closed for the duration of one time unit only, then when the relay tongue returns to its contact S the cable is insulated for the remaining length of the signal. Switching arrangements were provided for changing from this kind of transmission to the regular type and as far as could be determined the regular method gave the more permanent results. The method, however, is used on shorter lengths of cable of approximately 400 miles or so and apparently gives satisfactory results. Not having the constants of these cables and the speeds at which they are worked it is not possible to state here just how efficiently they

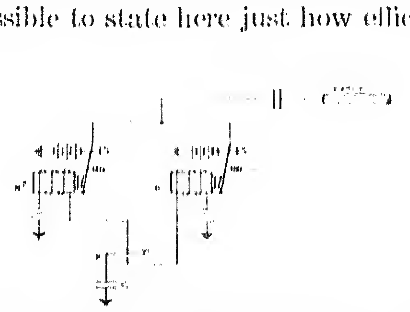

Fig. 11—Transmitting Connections for Suppressed Transmission. Insulating Method

are operated. As far as is known, they are operated under simplex conditions, which operation is hardly comparable with that of long duplexed cables.

Fig. 12 illustrates the suppressed insulating method of transmission in which A represents the standard block signals and B the suppressed signals with all but the first unit suppressed and the cable insulated during the time of suppression. At first glance the signals shown at A and B appear to be almost alike but if a zero line be drawn through the curves from X to X^1, it will be apparent that the prolongation of the current in B is less than in A.

Another form of transmission suggested is the unbroken or continuous alternating current transmission[7] employing three amplitudes, a large amplitude being used for a dash signal, a medium amplitude for the dot signal, and the smallest amplitude for the zero signal. Much consideration was given to the study of this type of cable transmission and experiments were carried out to determine its characteristics.

Curbed Transmission

Curbed transmission is old and has been in operation

Fig. 12 Showing Difference Between Standard and Suppressed Transmission. Insulating Method

since automatic transmission was first developed. It is a method whereby the sending battery is impressed upon the cable for only a portion of a time unit, the cable being earthed for the remainder of the time unit. Other methods of curbing have been employed whereby

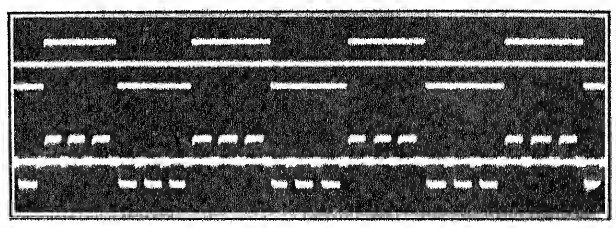

Fig. 13 Oscillogram of Standard and Curbed Transmission

a transmission time unit is divided into three elements instead of two as above mentioned. In some cases, perhaps 70 per cent of the time unit is transmitted with the maximum voltage, 20 per cent with a reversed lower voltage, and 10 per cent with earthing. By varying the curbing voltage and changing the degrees of curbing, various shapes of signals can be produced at the receiving end. Curbed transmission improves

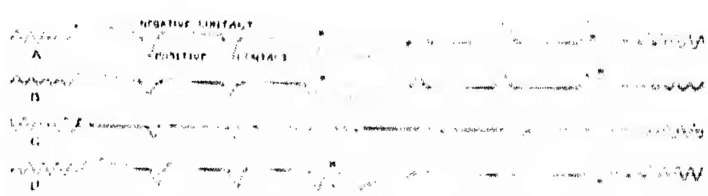

Fig. 13 Showing Received Signals Produced by Different Methods of Transmission

the shape of the received signals and correspondingly counteracts the effect of the variable lag. An illustration of curbed transmission is shown in Fig. 13 in which three-element block signals shown at A are transmitted as at B. The zero portion of the waves represents the time the cable is earthed between each element.

7. This method of transmission was suggested by General G. O. Squier.

Up to this point we have investigated four methods of transmission suggested for improving the reception of cable signals, namely:

1. Suppressed transmission earthing method.
2. Suppressed transmission insulating method.
3. Three amplitude transmission.
4. Curbed transmission.

To illustrate the characteristic cable effects on the received signals produced by some of the transmitting methods four groups of received signals are shown in Fig. 14, in which *A* represents received signals from block transmission, *B* curbed transmission, *C* suppressed transmission earthing method, and *D* suppressed transmission insulating method. The zero line running through the signals shows in the cases of *A*, *B*, and *D* that some of the wave crests which should have arrived on a negative contact have actually drifted to a positive contact and vice versa as indicated at *X*. In the case of *C*, all of the wave crests arrived on their respective contacts.

Shunted Condensers

In discussing the various methods of transmission and the reception of cable signals, the cable circuit represented in Fig. 5 shows the cable to be operated with unshunted sending and receiving condensers. Until recently this has been the standard method employed by the Western Union Telegraph Company for operating transatlantic cables, and the major part of the printer experiments were carried out under these conditions. Experiments were made with shunted condensers and further investigation is being made along these lines. The reason, as already stated, for using unshunted condensers is to prevent the flow of the low-frequency earth currents, more or less prevalent in transatlantic cables. So far as signal shape is concerned, it seems to be generally accepted that signal shape is better when the condensers are shunted.

Discussion

A. F. Connery: The method of cable signaling, suggested by Gulstad in 1898 and which is used in the operation of the printing telegraph system described by Mr. Angel, appears to be the only method available if the 5-unit 2-element code is to attempt to compete with the widely used 3-element unequal letter cable code on long cables. The application of this signaling method to the old-style duplex cables which span the Atlantic is no mean achievement, and many difficult and trying problems, of which little mention is made in the paper, must have been solved.

I note Mr. Angel states that the speed of a certain cable was increased from 300 to 375 letters per minute. I wonder whether net increase is meant. My impression has been that the signaling described in this paper, whereby the single-element impulses are attenuated in the cable and are generated locally in the receiver, requires a high grade of duplex balance which is difficult to secure and maintain. It would seem that the time lost in adjusting and regulating would be greater than for the older methods of transmission.

A large proportion of the cable traffic at the present time is in code, and each word usually has the same number of letters. In a number of codes, each group consists of ten letters. One advantage of the well-known 3-element cable code is the ease in which errors may be detected by the transcribing operator. A loss or gain of an impulse due to a change in balance, lightning kick, improper adjustment of apparatus, etc., at some relay station, will either make an unintelligible signal combination or will cause a 10-letter word, for example, to become a 9- or 11-letter word. In any case, the error is usually apparent to the transcribing operator who can have the doubtful part of the message repeated.

The 5-unit code does not possess this advantage, and the loss or gain of a pulse will cause a wrong letter to be printed in place of the proper letter. Each word will have the proper number of letters and the receiving operator will be unable to detect any irregularity.

For plain English traffic the printer on slow-speed cables is attractive, but for code traffic it appears to be at a disadvantage as compared to the widely used cable code.

The foregoing remarks do not apply to the new high-speed inductively loaded cables which must be multiplexed to secure satisfactory traffic distribution and have no duplex balances with which to contend.

W. A. Houghtaling: Mr. Angel's paper describes printer operation on ocean cables in its simple form, that is, single-channel operation or one printer and transmitter at each terminal of the cable. It may not be clearly understood, however, that the printer operation is not limited to a single-channel, as by the use of a rotary distributor, several channels are possible. In fact, two other cables are being operated with four and five channels respectively, and still another is operating with two channels.

The cable which is operating as a two-channel circuit is of the same type as that referred to in the paper, while the two which provide four and five channels are the loaded type.

One of the points brought out in Mr. Angel's paper that seems to me to be quite interesting is the way he has shown the various steps of increased output of a type of cable laid fifty years ago, obtained by the use of improved terminal apparatus and improved operating methods. It would seem that the cable engineers and cable manufacturers of half a century ago built better than they realized. This type of cable has been able to meet the ever increasing traffic requirements through all these years by means of the terminal improvements mentioned until it is now carrying more than five times the amount of traffic it could handle originally.

W. C. Peterman: The securing of the maximum message-carrying capacity of a cable which is the primary object of the cable engineer depends both on sending as many cycles per second of signaling current as possible over the cable and getting the greatest amount of intelligence out of every cycle of current. It was pointed out in the paper that as the transmitting frequency is increased, the attenuation of the signals becomes greater, and at the receiving end of the cable more and more amplification of the signals must be used in order to get current strong enough to operate the mechanical relays. Of course with vacuum-tube amplifiers the amount of amplification possible has been increased vastly over what was previously obtainable, but unfortunately it has been found that all of the amplification thus possible cannot be used in practise because of the presence of electrical disturbances. These disturbances may be either man-made, such as interference from nearby power lines or other cable circuits, or from the duplex balance of the cable itself; or they may be electrical disturbances from apparently natural sources of unknown origin.

The difficulty of receiving weak signals from distant radio broadcasting stations when any considerable amount of static is present, no matter how much amplification is available, is

familiar to everyone. In fact, greater amplification does not help at all after a certain point is reached; it only adds to the confusion. We have just about the same problem with receiving weak signals over a long cable. It thus becomes necessary to secure the greatest possible amount of information, as it were, from each received impulse, since we cannot increase without limit the number of impulses transmitted per second.

I just wish to emphasize, therefore, in the system described by Mr. Angel, and shown in his Fig. 1, that only the impulses of one-half the fundamental frequency must be received with sufficient strength to be well above the interference level, although we are getting the full amount of information out of the impulses transmitted at the fundamental frequency which impulses, by their very absence, because of greater attenuation, are caused to be filled in automatically at the receiving end. Thus we get the benefit of having to receive through the interference only, the comparatively stronger signals of one-half the working frequency while getting the full message-carrying advantage of the highest frequency impulses.

Herbert Angel: I should like to say, in reply to the comments by Mr. Connery, that the excellent method for increasing the speed of cables suggested by Mr. Gulstad in 1898, while quite successful for operating comparatively short lengths of cable, had never been found practicable to apply to long cables. This was pointed out by Messrs. Judd and Davies, of England, in their British patent of 1913, in which, for the first time, a method was described for filling in attenuated impulses for a synchronous system on long cables. The Western Union printing system does not use the Gulstad vibrating method for filling in the impulses.

Replying to Mr. Connery's query about the increased speed with printer operation, the output of 375 letters mentioned in the paper is a net output.

In reply to Mr. Connery's comment about the high-grade balance required for cable-printer operation, I should like to point out that in getting the 375-letter output which is an increase over the output obtained with cable Morse code, the frequency of the double received impulses is even then less than the maximum fundamental frequency when using cable Morse code. Therefore the received signaling impulses are larger and are better able to stand any slightly greater balance disturbance. Further, it has been found by repeated check, that under these conditions the cable printer is as accurate as the cable Morse code.

A Non-Rotary Regenerative Telegraph Repeater

BY A. F. CONNERY[1]

Associate, A. I. E. E.

Synopsis.—Rotary regenerative repeaters have made multiplex printing telegraphy possible over long distances. This paper gives a brief description of some types of rotary repeaters and then proceeds to describe in more detail a non-rotary regenerative repeater.

Introduction

THE use of multiple-channel printing telegraph systems in the United States and Canada has resulted in many problems in connection with their operation over long circuits.

Practically all circuits are duplexed and the usual practise is to repeater them at intervals of 250 to 350 mi. A printer circuit operated between New York and San Francisco may have as many as 12 repeaters.

An ordinary relay telegraph repeater can never repeat signals as perfectly formed as those sent out by the originating transmitter since the signals always arrive somewhat out of shape and the repeating apparatus itself contributes a further modification.

Most overhead telegraph circuits use a ground return and some distortion of the signals is inevitable in addition to the distortion caused by the repeaters and imperfections in the duplex balance.

To operate a transcontinental multiplex printing telegraph circuit equipped throughout with ordinary relay repeaters, a very high grade of line and repeater maintenance is required. Accurate duplex balances are essential at repeater and terminal stations. The most direct routes must be used and line conductors chosen which have a favored location on the pole line so as to reduce the cross-fire from other conductors.

Even with high grade maintenance, the signal received at the terminal station is somewhat distorted and much time is consumed in balancing and adjusting. It is apparent that even a slight distortion of the signal in each line section results, in the aggregate, in an extremely distorted signal being received at the terminal station. The speed of operation is very slow as compared with the shorter circuits and the traffic capacity is low.

By the use of a regenerative type of repeater, the received distorted signal in passing through the repeater is regenerated and sent on to the next line section in perfect shape. The invention of the regenerative repeater is old and is attributed to Baudot of France.

A regenerative repeater for duplex working usually consists of electrically driven tuning forks controlling synchronous motors, rotary distributors driven by the synchronous motors, a plurality of storing relays together with the line relays and relays used in the synchronizing circuit. The synchronizing circuit maintains the distributor in step with the received signals.

Fig. 1 indicates a simple form of regenerative repeater. The sent, received, and regenerated signals are shown in addition to the two rings, $R1$ and $R2$, of the rotary distributor. The received signals operate line relay $L\,R$. Transmitting relay $T\,R$ can only be operated by $L\,R$ during the period that brush $B\,R$ has joined $R1$ to a segment of $R2$. The only part of the received signal utilized for retransmission is that marked S. Any distortion occurring outside

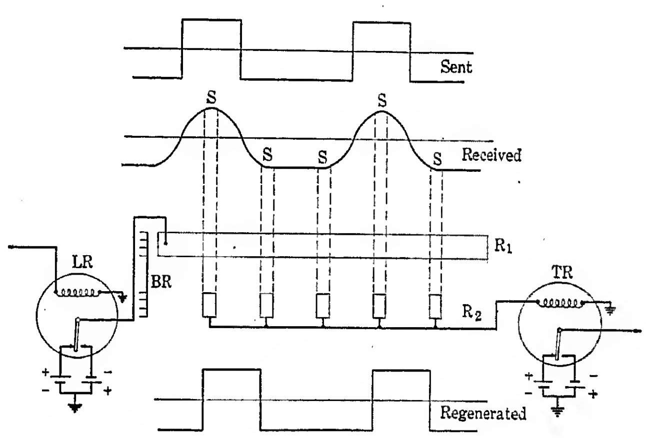

FIG. 1

of S will have no effect on the retransmitted signal. With this type of repeater, a slight distortion may be present in the retransmitted signals if the received signals are so badly distorted that they infringe upon S. Reducing the length of the segments $R2$ increases the ability of the repeater to regenerate badly distorted signals, but, if the segments are too short, the operating impulse to transmitting relay $T\,R$ may become too short to properly actuate the relay. The brushes $B\,R$ must be driven at such a speed that the time required for the brush to pass from the start of one segment to the start of the next segment is the same as the time occupied by the shortest signal element.

Fig. 2 indicates a form of regenerative repeater which was invented by P. M. Rainey. Only a portion of the distributor face is shown. Line relay $L\,R$ is actuated by signals received over line 1. Brush $B\,R1$ connects successively the receiving segments of $R2$ to $R1$. The storing relays, $S\,R1$ to $S\,R5$, are operated whenever the line relay tongue is touching its marking contact at

1. Telegraph Engineer, Postal Telegraph Cable Co., 253 Broadway, New York, N. Y.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

the same instant that the brush makes contact with the respective segments of $R2$. Each storing relay, when operated, locks up through the left contact and tongue and the right contact applies the proper polarity of battery to the transmitting segments $R4$. Transmitting brush $B\,R2$, which is angularly displaced with respect to $B\,R1$, connects line 2 to the successive transmitting segments. When the transmission is

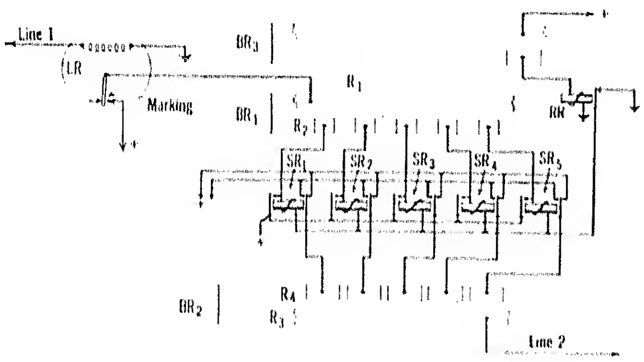

Fig. 2

completed, the restoring relay $R\,R$ is actuated by $B\,R3$. This unlocks the storing relays and they are ready for the next revolution of the brushes.

Fig. 3 illustrates still another form of regenerative repeater. The polarized storing relays $S\,R1$ and $S\,R2$ are connected to alternate segments on the sending and receiving rings. While a signal from line 1 is being

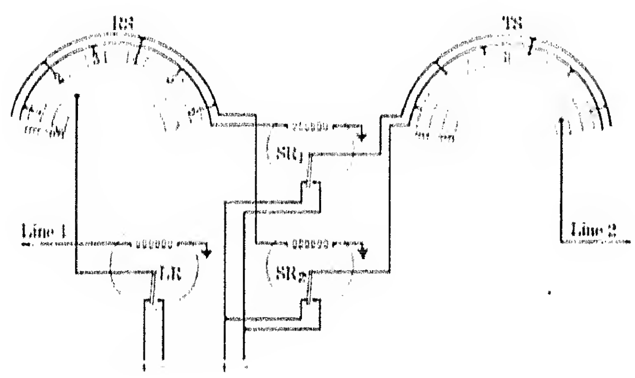

Fig. 3

stored in one relay, the stored signal in the other relay is being transmitted to line 2.

There are two main types of synchronizing systems used to maintain phase relation between the distributor brush arms and the received signals. One type, which has been termed "shift the hands" correction, shifts the brush arms to maintain synchronism while the other type maintains synchronism by altering the natural period of the driving fork.

In one example of the "shift the hands" correction, the rotary distributor is arranged to run slightly faster and a mechanism controlled by the received signals steps back or "corrects" the distributor brushes when they gain a certain amount over the brushes of the sending distributor. Several opportunities for correction are available during each revolution. While this correcting scheme has been used to a considerable extent on rotary regenerative repeaters, it is open to some objections. The many opportunities for correction in each revolution make it possible for a few badly distorted signals to considerably alter the phase relations and several seconds are required for the distributor to work around to the proper phase. When several repeaters of this type are used in tandem on a long circuit, difficulty may be experienced in holding synchronism.

In the writer's opinion, it is preferable to use, in a regenerative repeater, a correction which alters the natural period of the driving fork because the correcting action is gradual and an occasional badly distorted signal will not seriously alter the phase relations.

Non-Rotary Regenerative Repeater

The main object of this paper is to describe a new type of regenerative repeater which has no rotating parts. It should be realized in this connection that the rotating feature of the repeaters previously described in this

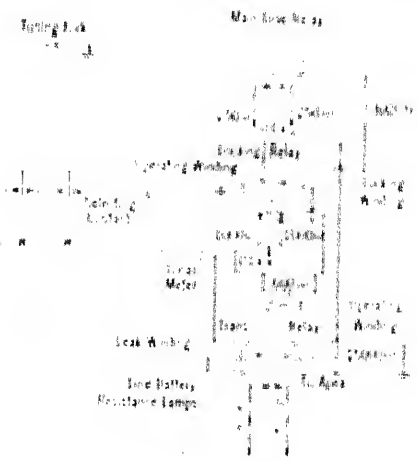

Fig. 4

paper has for its object the control of electrical contacts at uniform time intervals which agree with the rate at which signals are being sent over the line circuit. An electrically operated tuning fork adjusted to vibrate at a uniform rate and controlling electrical contacts, can be used, therefore, for timing purposes for regenerative telegraph repeaters and rotating members eliminated. A repeater for one-way repetition consists essentially, therefore, of an electrically operated tuning fork, a line relay, a locking relay, a transmitting relay and a correcting or synchronizing circuit with relays. It has been found possible in practise to make use of the same type of tuning fork as is now used with multiplex printing telegraph terminal sets.

Selecting Circuit

Fig. 4 shows the selecting and locking circuits. The locking relay is normally under the influence of the main line relay which controls the direction of the current through the operating winding. The current through

the locking winding of the locking relay is stronger than the current in the operating winding and as long as the fork is touching its selecting contact the armature of the locking relay is prevented from moving. During the period that the fork is not touching the selecting contact, no current flows through the locking winding of the locking relay, and it therefore is under the influence of the tongue of the main line relay. The polarity of the signal transmitted by the transmitting relay depends upon the position of the tongue of the locking relay at the moment the fork engages its selecting contact. A long duration of engagement of the fork with the selecting contact does not injure the repeated

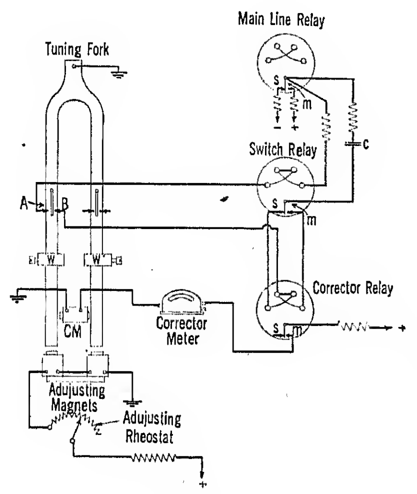

Fig. 5

signals. The locking up of the locking relay while the transmitting relay is operated prevents any clipping of the signals sent out from the transmitting relay. The shunted condenser permits a quick rise and fall of current in the locking winding. A leak current through one of the windings of the transmitting relay tends to hold the relay tongue to whichever contact it may be touching. The current in the leak winding is small and does not interfere with the operation of the relay. The local meter is used as a guide in checking speed and detecting breakups.

Correction Circuit

The means used to hold the fork in synchronism with received signals is an adaptation of the Picard system.

Fig. 5 shows the correction circuit.

By means of the weights W and the adjusting rheostat, the rate of vibration of the fork is set so that, with no current flowing through the corrector magnet $C\,M$, it makes slightly less than a complete cycle of vibration for each unit length of line signal. With current flowing through the corrector magnet, the fork speed increases so that it makes slightly more than a complete cycle of vibration for each unit length of line signal. In actual operation, the current through the corrector magnet occurs at irregular intervals due to the action of the correction circuit and the fork is held in step with the received signals. When the fork falls behind the signals, current flows through the corrector magnet and causes the fork speed to increase. When the fork gains on the signals, the current is cut off the corrector magnet and the fork speed is reduced.

Assume, for example, that the speed has been matched and the repeater is in operation. If the tongue of the main line relay moves from one of its contacts to the other at the instant the fork is touching contact A, Fig. 5, the tongue of the switch relay $S\,R$ is moved to correspond with the position of the tongue of relay $M\,L\,R$. When the fork makes contact with B, a short impulse of current flows through condenser C and one winding of the corrector relay and the tongue of relay $C\,R$ is moved to the marking contact and current flows through the corrector magnet and increases the speed of the fork. As long as the movements of the tongue of the main line relay $M\,L\,R$ occur at the instant that the fork is touching contact A, the relay $C\,R$ remains in the marking position. If, for example, the movement of the tongue of relay $M\,L\,R$ is from S to M, the tongue of relay $S\,R$ is moved to contact M and the current impulse through the condenser and the windings of relay $C\,R$ which occurs when the fork touches contact B goes through one winding of relay $C\,R$ from right to left and the tongue is thrown to the right. If, however, the movement of the tongue of relay $M\,L\,R$ is from M to S, the tongue of relay $S\,R$ is moved to contact S and the current impulse which occurs when the fork touches contact B is in a reverse direction, but goes through the other winding of the relay $C\,R$ from right to left and the tongue still tends to be thrown to the right.

The tongue of relay $C\,R$ being on contact M, a current flows, through the corrector magnet which increases the speed of the fork. In a short time the movements of the tongue of relay $M\,L\,R$ occur when the fork is on contact B. The impulse through the condenser occurs just as soon as the tongue of relay $M\,L\,R$ moves and as the relay $S\,R$ is not affected since the fork is on contact B, the impulse through the condenser moves the tongue of relay $C\,R$ to the left and the current is cut off the corrector magnet.

In reviewing the action of the correction circuit, it is apparent that if the operation of the tongue of relay $M\,L\,R$ occurs when the fork is touching contact A, the switch relay tongue is moved and the impulse through the condenser which takes place when the fork moves to contact B throws the tongue of relay $C\,R$ to the right and the fork speed increases. If the operation of the tongue of relay $M\,L\,R$ occurs when the fork is touching contact B, the impulse through the condenser occurs immediately and since relay $S\,R$ has not been operated, the impulse moves the tongue of the relay $C\,R$ to the spacing or left-hand position. This breaks the current through the corrector magnet and the fork speed will reduce again. In actual

operation, the fork corrector contact is moving from A to B or about to move when the tongue of relay $M\ L\ R$ operates.

Regenerative Action

The correction circuit, as explained, holds the tuning fork in step with the line signals. The fork makes a complete cycle of vibration during the time of the shortest signal element. If, for example, the signals over the line are the equivalent of alternating current

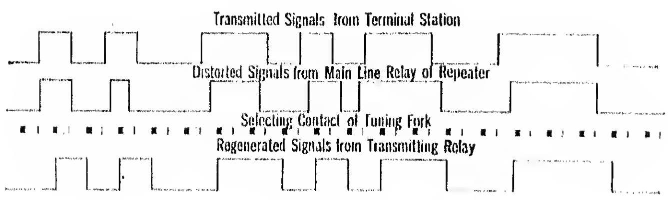

Fig. 6

at a frequency of 25 cycles or 50 signal units per sec., the fork vibrates at 50 cycles.

The received signals operate the main line relay which in turn operates the locking relay. The fork engages the selecting contact once for each unit length of received signal. The instant that the signal reverses on the transmitting relay is defined by the vibration of the fork into a contact with the selecting contact. The tuning fork maintains a constant rate of vibration and the repeated signals reverse at properly timed intervals.

Fig. 6 shows in a graphic form the transmitted, received, and regenerated signals. The comparatively

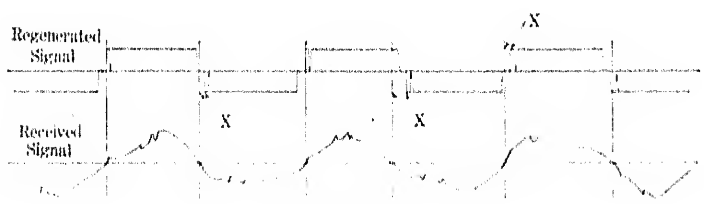

Fig. 7

long time during which the fork engages the selecting contact insures that the transmitting relay will be reliably operated and will tend to minimize chatter. Fig. 7 is a tracing from an oscillogram of some distorted received signals and their reconstruction by the repeater. The received signals were in the form of continuous reversals or alternating current. The variation in the distance between the points marked X would be the amount of distortion retransmitted by an ordinary relay repeater. The initial part of each regenerated signal shows a slight bounce or chatter of the transmitting relay contacts. Improved relays are now available, the use of which will reduce the chatter effect.

The range of speed of the repeater using a standard tuning fork is from 15 to 30 cycles line frequency or 30 to 60 words per min. per channel of a two-channel, five-unit code printer circuit.

In the early development of this regenerative repeater, means were provided for varying the selecting or pickup point, thus giving the equivalent of orienting the contact segments of a rotary distributor. The correcting system which was adopted, however, proved to be very stable and it was found that the orienting feature could be dispensed with. Within the 15- to 30-cycle line frequency range, the point of selecting under all conditions is as close to the central portion of the signal as could be desired. In this connection it should be pointed out that an orienting feature is of less value at a regenerative repeater station where no printer record is available than on a printer terminal set. Valuable time is often lost in making futile adjustments of the orientation when another remedy is required.

Alternating Current for Balancing

One advantage of regenerative repeaters is the possibility of reducing the time required for balancing. If, for example, a long line circuit is equipped with a

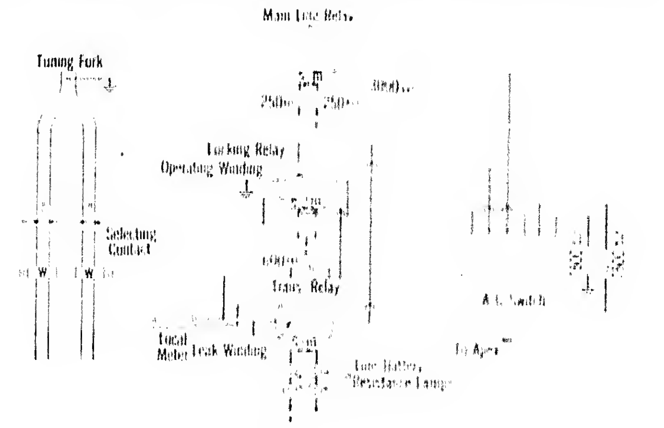

Fig. 8

regenerative repeater at a central point, a readjustment or lineup of the balances of the relay repeaters on one side of the regenerative station may be conducted at the same time as the lineup on the other side. The regenerative repeater, however, must be equipped with a means of transmitting alternating current to either line, and it should preferably be of nearly the same frequency as that at which the working signals are transmitted.

Fig. 8 shows how this is accomplished on the non-rotary repeater without the need for additional equipment with the exception of the a-c. switch.

In the normal right-hand position of the a-c. switch, the operating winding of the locking relay is connected to the tongue of the main line relay and the leak winding of the transmitting relay goes to ground through 15,000 ohms. When the levers of the a-c. switch are thrown to the left, the operating winding of the locking relay is connected through the leak winding of the transmitting relay to the tongue of the same relay, through a 7500-ohm resistance. This leak current through the operating winding of the locking relay normally holds the tongue of the locking relay in a position opposite to

that of the transmitting relay. When the fork engages the selecting contact, the tongue of the transmitting relay moves in the usual manner to a position corresponding with that of the locking relay. When the tongue of the transmitting relay operates, the current through the operating winding of the locking relay reverses but the locking relay is not operated immediately because the stronger current in its locking winding prevents its operation. When the fork moves away from the selecting contact, the locking current ceases to flow and the locking relay tongue, under the influence of the leak current from the transmitting relay, moves to the opposite contact.

From the foregoing, it is apparent that when the fork engages its selecting contact, the transmitting relay tongue moves to a similar position to that of the locking relay and when the fork disengages the selecting contact, the locking relay tongue moves to a dissimilar position to that of the transmitting relay. The alternating current generated in this manner is practically the same frequency as the alternating current from the terminal multiplex distributor.

Conversion to Plain Repeater

The repeater is equipped with cords and jacks by the use of which the regenerative action can be cut out and the set will function as a non-regenerative repeater.

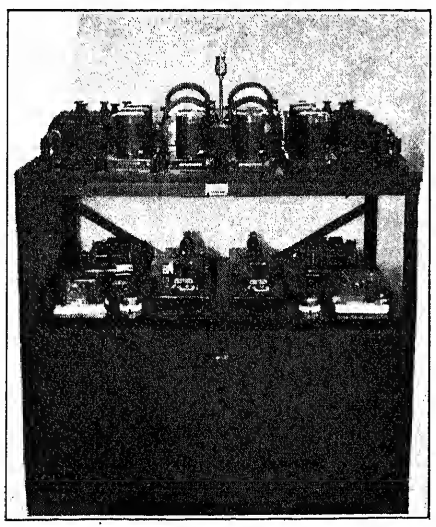

Fig. 9

Floor Space and Power Requirements

The complete duplex repeater is shown in Fig. 9.

The repeater table is shipped completely wired for duplex operation. It is merely necessary to connect to power, lines, and ground and attach the forks and relays, etc., to the table. The floor space required is 43 in. by 27 in. The height of the table is 42 in.

The tuning fork, which is similar to those used on the terminal multiplex sets, is shown in Fig. 10.

The local power may be either 110 or 160 volts. The local current required for the duplex table is approximately one-half ampere and it has been found possible to install these repeaters in most telegraph offices without adding to the generator plant.

Operating Experience in Postal Telegraph-Cable System

More than 50 of these repeaters are in use.

No difficulty has been experienced in operating several repeaters in one printer circuit.

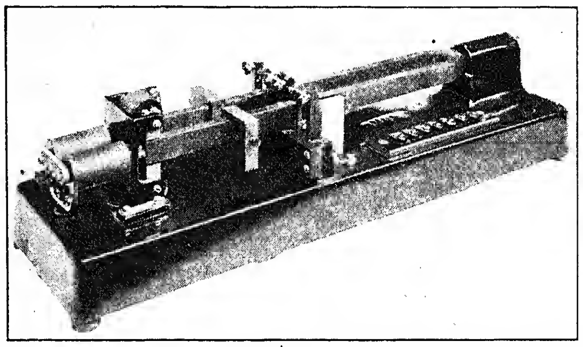

Fig. 10

Before regenerative repeaters were used, it was necessary to assign the best line wires to the overland circuits so that the overall distortion of the signal would be kept at a minimum. The present practise is to use a sufficient number of regenerative repeaters so that almost any line wire, provided it is electrically intact and free from swings, may be used in the overland circuits.

In several instances, wire routes which were unsuitable for use in overland circuits because of the long distances between repeater stations and which had insufficient wires to justify opening up additional repeater stations, have been made suitable for printer operation by the installation of regenerative repeaters adjacent to or near the long sections.

Fig. 11 shows the layout of two typical overland circuits. The speed of operation is approximately 50 words per min. per channel and the spacing between the regenerative repeaters is short enough to reduce lineups to minimum.

One or more regenerative repeaters are used in practically every printer circuit over 800 mi. in length with consequent reduction in lost circuit time and increase in speed of operation.

Conclusion

This regenerative repeater was developed to provide a simple and compact form of repeater which would give equivalent results to those obtained from the rotary regenerator without the expense of the rotary distributors and their synchronous motors.

The design eliminated the necessity for special types of distributors which otherwise would have had to be built to regenerate the multiplex circuits in use on the lines of the Postal Telegraph Cable Company.

The completed non-rotary regenerative repeaters have certain economies and improvements over the rotary forms considered and among these were:

The first cost is less because the expensive distributors and synchronous motors with accessories are eliminated.

The maintenance cost is lower because there are no distributor parts to require attention and renewal and less local current is needed.

The required amount of floor space is reduced.

The regeneration of the signals being accomplished directly by the fork eliminates the loss in margin caused by the tendency of the distributors to hunt.

A short interruption of the local power supply does not necessitate the attention of a repeater attendant. The tuning forks are self-starting and when the power supply is resumed the repeater starts up automatically.

Discussion

W. C. Peterman: I should like to point out that a type of rotary repeater differing from those shown in Figs. 1, 2, and 3 in Mr. Connery's paper is shown in Fig. 2 of the paper by Herbert Angel[1].

In the type of rotary shown by Mr. Angel, which has been used very successfully by the Western Union on their long ocean cable circuits, the pick-up circuit is separate from the locking and sending-on relay circuit although they are both connected to segments on the same segmented rings. This regenerator gives complete regeneration; that is to say, if an impulse is received of sufficient duration to be locked up, the regenerated signal is of a definite duration.

In this respect it is the equivalent of the rotary repeater shown in Mr. Connery's Fig. 3, although it uses but one segmented ring and two unbiased relays when regenerating two-current signals, which tends for simplification. The repeater as shown in Fig. 2, however, is wired for cable Morse three-current signals and, therefore, uses four biased relays.

Herbert Angel: Considerable work has been done by the Western Union Telegraph Company with regenerative repeaters of both the rotary and non-rotary types, the latter being known as the fork regenerative repeater. Opinions differ as to which is the more advantageous type to use; each probably has its special field.

In a great many cases it has been found more desirable to use the rotary type with segmented rings for leaking off printers. Aside from this there is the question of brush transmission in one case and relay contact transmission in the other. It is the more general opinion that brush transmission is superior to relay contact transmission. For higher speeds the rotary type should be more reliable than the fork type as now developed.

A. F. Connery: Answering Mr. Peterman's comments, the diagrams of the rotary repeaters shown were of course made as simple as possible, and on some of them it would be necessary to add accessories to make practical repeaters such for example, as locking up the polarized transmitting relays to make them less subject to vibration and things like that.

We do not make claim for the non-rotary repeater that it will send out a better signal than a rotary repeater, but the advantage is that it is simpler and easier to maintain, and we think that in the hands of the average attendants, the net results will be better.

There are some purposes for which the rotary repeater is better; for instance, where we want drop-channel and other circuits like them. When we want to get into complicated circuits it is better simply to add segmented rings on the rotary mechanism, but on a straightforward regenerative repeater I think there are some advantages for the non-rotary repeater.

Mr. Angel's comments upon the advantages of brush transmission over relay transmission are well founded. In fact until recently there was a very decided advantage of brush transmission over relay, but relays have recently been developed with very low transit time; that is, the relays travel from one contact to the other at very high speed and means of reducing chatter have been developed so that now I think brush transmission has very little if any advantage over relay transmission and of course there is less maintenance of the relay contacts.

Electrical Reproduction from Phonograph Records

BY EDWARD W. KELLOGG[1]

Associate, A. I. E. E.

Synopsis.—*A new and improved tool generally means new or nproved accomplishments. Great improvements in sound recordng and reproduction have been made possible by the thermionic mplifier.*

Electrical reproduction may be considered in three steps, (1) eneration of a voltage by the vibrations of the needle, (2) amplificaon, (3) conversion of electrical power into sound. The first f these steps involves some interesting mechanical and electrical roblems, and it is with these that the paper primarily deals, the roblems of amplification and loud speaker design having been iscussed in earlier publications to which references are given. Several types of phonograph "pick up" are possible; electrostatic, piezoelectric, electromagnetic, and variable resistance or microphonic. The electromagnetic principle is used in the device now manufactured. Since the moving armature cannot be actually at the needle tip, the little generator must function by transmitting the vibrations from the needle tip through a more or less flexible structure to the armature. Vibrations are inevitably transmitted, but when the requirements of freedom from appreciable distortion and maximum possible output are added, extreme care in design becomes necessary. An analysis is given of the mechanical behavior of the present model of reproducer.

MANY interesting improvements have been made recently in methods for recording and reproducing sound, which have resulted in truer and more leasing reproduction. These have involved the use of lectrical means in recording, while both electrical and irect or mechanical systems are being used with good esults for reproduction. A discussion of some of the roblems arising in an electrical system of reproduction, eems warranted in view of the widespread interest in uch questions and of the fundamental nature of some f the mechanical problems involved.

Mechanical and Electrical Systems Compared. The inerent advantage of the electrical method of phonoraphic recording and reproduction, as compared with the lder direct methods, lies in the fact that the electrical nethods can make use of amplifiers. In the old ystem of recording, the cutting tool was mechanially connected to a diaphragm which was actuated y sound waves. The power available to give the ecessary vibrations to the tool was thus limited to hat could be collected from the original sound. In he case of electrical recording the power for vibrating he tool may be made as great as needed. This does ot necessarily mean louder records or greater amplitude of vibrations. In acoustic apparatus extreme ensitivity is generally purchased at the expense of uality. In order to get sufficient amplitudes of cutting ool vibration, a horn was used to concentrate the sound vaves, and a resonant diaphragm was employed. Both f these introduce distortion. In electrical recording, sound pick up or transmitter without a horn is used. ts electrical output is small, but can be amplified withut appreciable distortion, and relatively large forces an be applied magnetically to the cutting tool, which nay now be heavily damped, thereby reducing its tendency to respond more to certain frequencies in the musical scale than to others.

When we come to the problem of reproduction from the record, the possibility of amplification does not give so great an advantage to the electrical system, as in the recording, because the reproducing needle, unlike the sound waves with which we started, can deliver considerable power, or apply large forces to the object which it is required to vibrate. This power at the reproducing needle is, of course, derived from the rotation of the record. In fact, cutting a record and then playing it may be regarded as a method of power amplification. In the old method of cutting and reproduction the power output in sound from the phonograph is normally many times the power collected by the horn used in recording.

Both the mechanical and electrical systems can be so designed as to give a very high order of quality in reproduction. The advantage of the mechanical system is its simplicity. The advantages of the electrical system are its flexibility, ease of adjusting loudness, and the possibility of obtaining greater volume of sound, where this is desired and the apparatus is designed accordingly.

Electrical reproduction may be considered in three steps, (1) the vibration of the needle must be made to generate a voltage whose wave form corresponds to the wave in the groove, (2) this voltage is amplified, and (3) an electrical loud speaker converts electrical power back into sound. The design of amplifiers and loud speakers has been discussed in earlier papers[2]. The present paper will, therefore, deal principally with the device in which the vibration of the needle generates the voltage which is to be supplied to the amplifier.

Possible Types of Reproducer

The same principles by which diaphragm vibrations in a transmitter are made to produce voice currents, may be applied to the case of the phonograph reproducer. Many types of transmitters have been used, among which are the magnetophone (Bell's first transmitter as well as receiver) the variable resistance transmitter such as in general use in telephony, the condenser transmitter[3] which is used in broadcasting stations, and a transmitter making use of a piezo-electric[4] crystal. These transmitters may be classified as of two types: (1) those in which the output voltage is proportional to the deflection, and (2) those in which the output voltage depends on the velocity of diaphragm movement. The carbon microphone, condenser, and piezoelectric transmitters as generally used are of the first type, while the magnetophone belongs to the second or velocity type. The condenser transmitter, for example, is kept charged through a very high resistance so that the charge upon the plates cannot change appreciably during an audio cycle. The voltage across the condenser then varies inversely as the capacity, or directly as the plate spacing. The voltage thus obtained which is applied to the grid of an amplifier tube is proportional to diaphragm deflection, independent of frequency except for frequencies so low that the condenser reactance is considerable compared with the leak resistance (for practical purposes we may say equal to the leak resistance). The same considerations apply to the piezoelectric crystal which may be regarded as a condenser of constant capacity but variable charge, the charge depending on the mechanical force applied to the crystal. On the other hand, both the condenser transmitter and the piezoelectric crystal may be made to act as velocity devices by using leaks whose resistance is low compared with the capacity reactance of the condenser throughout the essential frequency range. In this case the charge flows freely back and forth through the resistance, and the current (or voltage across the leak resistance) is proportional to the rate of change of charge which in turn is proportional to the diaphragm velocity. The magnetic transmitter works on the principle of changing the magnetic flux through a coil. Its open circuit voltage is proportional to the rate of change of the flux, and this again depends on velocity of movement. In terms of sine waves, the deflection devices (type No. 1) give a voltage proportional to amplitude independent of frequency, while the velocity devices (type No. 2) give a voltage proportional to amplitude multiplied by frequency.

Which of these types of device should we choose for a phonograph reproducer? If the system by which the record is cut is so designed that the deflection of the cutting point is proportional to the original sound wave pressure, then a deflection type reproducer is required. If the record is cut by a tool whose instantaneous velocity is proportional to the sound wave pressure, we shall require a velocity type reproducer. Both systems are equally correct from the standpoint that if their conditions are complied with, distortionless reproduction will result. The choice can, therefore, rest on such considerations as scratch noise ratio, wearing qualities of record, interchangeability of records, and designing a practical device which performs in accordance with the theoretical requirements. By interchangeability of records is meant that it is desirable that the electrical reproducing system shall not only give good results with records that are especially cut for it, but so far as possible give pleasing results with records cut by the old process, and the records which are correctly cut for electrical reproduction should sound well when played on a horn type machine. This requirement is most nearly met by the velocity system of cutting and reproducing. When a diaphragm is placed at the end of a long pipe it produces sound wave pressures in the pipe proportional to the diaphragm velocity. If, instead of a pipe, the diaphragm works into a horn of the usual (approximately exponential) shape, the same relation holds, very nearly, over most of the frequency range, the difference being that below a certain frequency the sound radiation from the horn drops to almost nothing[5]. If the needle motion is properly imparted to the diaphragm, a phonograph of the horn type may be regarded as a device giving output sound pressure proportional to needle velocity, except that its response is limited to frequencies above a certain value. In some of the new designs employing long slowly expanding horns, the range of response has been greatly extended in the direction of response to lower tones, this change plus the reduction of resonances in the system makes of the horn phonograph a machine which holds very closely to the relation output sound pressure proportional to needle velocity. It is, therefore, clear that if the electrical reproducing system is to be such that records may be satisfactorily interchanged, it must work on the velocity principle. It is not apparent that in respect to wear of records and scratch ratio a system in which output depended on deflection rather than velocity would have any advantages to offset the disadvantage of not having the records interchangeable.

Of the possible devices giving voltage proportional to needle velocity, the magnetic and the piezoelectric

have both been proved practicable, and the condenser is unquestionably a possibility. A very satisfactory design employing a piezoelectric crystal was worked out by Mr. Chester W. Rice of the General Electric Company. The magnetic reproducer gave substantially the same results, and was chosen on account of manufacturing considerations. It is the mechanical problems involved in the design of this device which are of especial interest.

The Magnetic Reproducing Device or Phonograph Pick-Up

Fig. 1 shows in outline several possible forms of magnetic reproducer for use with records having laterally cut grooves (as distinguished from grooves of

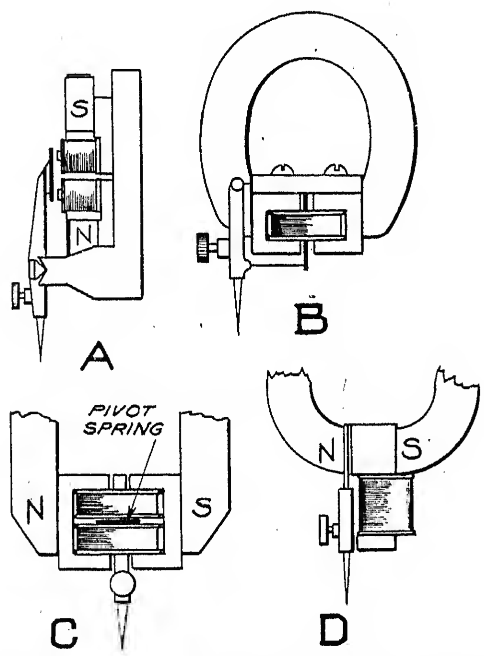

Fig. 1—Several Possible Types of Magnetic Phonograph Pick-Up

varying depth). In each of these a movement of the needle causes a change in the flux through the coil or coils, and the voltage induced depends on the rate at which this flux changes, or on the velocity of movement of the iron armature. If there are no short-circuited turns, if the winding is electrically unloaded, and if the iron parts are of low reluctance at all frequencies compared with the air-gaps, the faithfulness of reproduction depends entirely on the similarity of motion of the armature and needle point. If the structures were rigid this similarity would be perfect and distortion would be nil.

Very little power is absorbed by the moving iron armature, for the winding is virtually unloaded, and even if the winding were loaded through a resistance, the power absorption would not be sufficient to produce much damping. There is, however, considerable stiffness in the mounting of the armature, necessary to resist the magnetic pull.

The mechanical problem may then be stated as follows: Given a certain movement of the needle tip, a motion of identical form must be imparted to a small magnetic element at an appreciable distance from the needle tip, displacement of the magnetic element from its main position being resisted by a spring or its equivalent. There are three types of structure by which

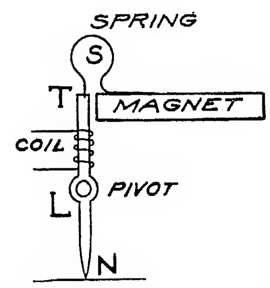

Fig. 2—Essential Features of a Magnetic Pick-Up

the vibratory motion might be transmitted and the requirement of identical wave form be fulfilled: (1) a rigid structure, (2) a spring potentiometer, (3) a filter type or wave transmission structure. Fig. 2 shows a magnetic reproducing device or pick-up in schematic form. The only way in which the motion of the end T can differ in wave form from that at N is by bending of the lever or give at the pivot. In other words, making the system rigid will prevent distortion. But freedom from distortion is also compatible with flexibility in the lever and needle. If the needle point is pushed to one side of its normal position the yield is partly in the lever and partly in the spring S, the amount of motion at T depending on the relative stiffness of the two. I have called this a "spring potentiometer," by analogy with the electrical potentiometer. If two springs are connected in series as indicated in Fig. 3 the motion of the junction point T is a certain fraction of the motion at N. The ratio is only constant, however, if mass plays no appreciable part. If a mass is located at T the motion

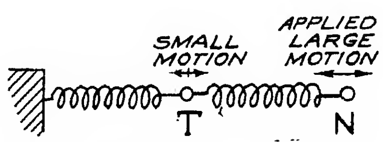

Fig. 3—Spring Potentiometer

of the point T will be practically the same as though there were no mass present, provided the natural frequency determined by the mass in conjunction with the two springs is well above the highest frequency applied at N. The third type of structure by which the motion at N can be accurately reproduced at T is one in which both flexibility and mass are distributed. The distribution need not necessarily be uniform but the masses and flexible elements must have certain relations which depend on the range of frequencies to be transmitted. In this case there is definite wave motion

and progressive phase differences between the motions of the successive parts of the structure. Because the masses and flexible elements are lumped rather than uniformly distributed, the wave motion structure has the properties of a filter, and has been called the "filter type structure" by Messrs. Maxfield and Harrison in their discussion of recording and direct or mechanical phonograph reproduction[6]. If the distance through which it is desired to transmit acoustic vibrations is of the order of several inches it becomes practically impossible to construct a rigid mechanical transmission, or one in which mass plays negligible part. Wave motion becomes inevitable, and to secure distortionless transmission it is necessary to so design the system that the waves will not be reflected. This means a proper proportioning of the mass and flexibility of each part, and the final absorption of the wave energy in a mechanical resistance of the correct value. If these conditions are met there is practically no limit to the distance to which the vibrations may be accurately transmitted. In the case of mechanical reproduction from a laterally cut phonograph record the necessary distance from needle point to diaphragm is too great for a truly rigid connection, while the mechanical resistance necessary for proper wave transmission is obtainable from the reaction of air on the diaphragm. The wave or filter system was, therefore, the logical choice.

For the electromagnetic reproducer on the other hand there appeared to be a possibility of making the distance short enough and the parts light enough so that a good approximation to a rigid structure could be obtained. If this should prove possible, the design would be much simplified, the required exactness of duplication would be reduced, and the necessity of obtaining a pure mechanical resistance would be avoided.

In considering the design of a magnetic reproducer it is necessary to choose between several possible types, such as moving-coil as against moving-magnetic armature, center-pivoted or full rocker as against end-pivoted or half rocker, windings on poles as against winding on armature. Several of these possible types are illustrated in Fig. 4.

The moving coil arrangement involves a long air-gap and, therefore, a heavy field magnet. Moreover the mass of the coil is objectionably large. Devices with iron armatures which move toward and away from the poles of a magnet have better possibility of producing a large change of flux interlinkage with a small movement of a small mass.

Again, there is decided choice between the various magnetic armature arrangements. In the first place it is better to place the windings around the armature than around the poles for much of the flux change in the armature involves only a slight shift of the flux from the pole pieces and does not cut all the turns of a coil wound on the pole. Hence we may limit our choice to column III.

Next is the question of single acting vs. double acting or "push pull" arrangements. Comparing k with j of Fig. 4, for example, we may say that adding the two poles on the left hand side of the armature has doubled the magnetic effect which results from a given motion of the armature, for there are just twice as many air-gaps whose reluctance is varied. Moreover, by placing opposite poles on the two sides we have reduced the steady flux which the armature has to carry, leaving only the residual or alternating flux. Hence the armature may actually be lighter in k than in j. Again, the rocker type armature has an advantage over the translation type armature in which both ends move in the same direction. It is only the motion of the ends of the armature opposite the poles which is effective to produce flux change. In the translation type all parts of the armature move equally, whereas in the rocker type, the middle has only slight motion for a given motion at the ends.

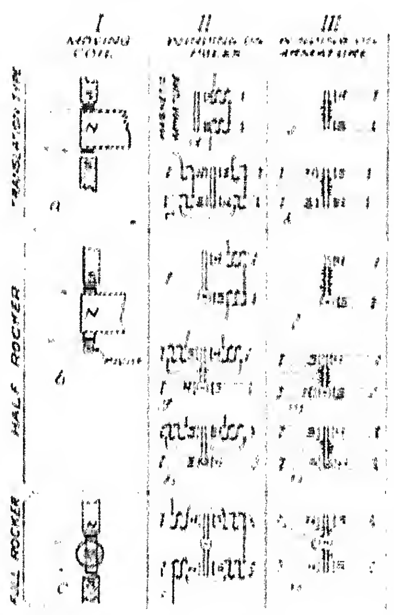

Fig. 4 Magnetic Systems Available for Reproducing Devices

We have now reduced the choice to the half rocker as compared with the full rocker. The middle of the armature of the full rocker is a point of constant magnetic potential. If we imagine the armature cut in two and only the upper end moved, we should still get as much flux change through the upper end of the armature as we did in the full rocker, provided we could keep the lower end of the moving portion at constant magnetic potential. In other words, we might say that in the full rocker type the motion of the upper half gives rise to the flux change and that the motion of the lower end is required to keep the middle at constant magnetic potential. In the half rocker the pivot end of the armature can be kept at *nearly* constant magnetic potential

6. *High Quality Recording and Reproducing of Music and Speech.* J. P. Maxfield and H. C. Harrison, A. I. E. E., Feb. 1926, *Bell System Tech. Jour.*, July, 1926.

by making the reluctance of the air-gaps at this end low compared with that of the gaps at the moving end. For example if the reluctance of the gaps at the pivot end is equal to that of the moving end gaps the flux variation will be half as much as in the full rocker, while if the pivot end gaps have one-fourth the reluctance of the moving end gaps, the flux variation in the armature will be eight-tenths as much as in the full rocker. This assumes negligible magnetic potential consumed in the armature and pole pieces, compared with that used in the gaps. It appears then that the half rocker is not necessarily at great disadvantage compared with the full rocker from the magnetic standpoint, and we shall see that it lends itself better to meeting the mechanical design requirements. The foregoing comparison of magnetic systems does not take into account the possible power output of the winding, nor is the elastic stiffness required to hold the armature in its mean position allowed to weigh in the choice. The comparison is wholly from the standpoint of obtaining the maximum open-circuit voltage with the minimum effective inertia of moving parts.

It is desirable that the magnetic reproducer shall utilize needles of about the size already in use. This means that the needle clamping screw must be within about ⅝ in. of the record. The screw is a potential source of trouble, first because it adds mass to the moving system and secondly because it has its own natural

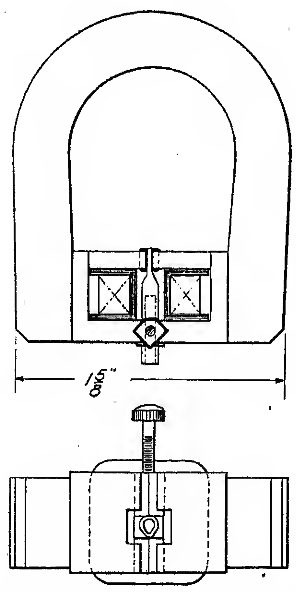

Fig. 5—Magnetic Phonograph Pick-Up as Manufactured

frequency of vibration which reacts on the motion of the armature producing both an anti-resonance and a resonance. If the screw is very short and stiff its natural frequency may be high enough to avoid detrimental effect, but the problem may then be to make it conveniently accessible. The types of device shown in Fig. 1 depend on using a short stiff screw. In designs of the type shown in Fig. 1B the set screw was accessible but these devices were found to depart too far from rigid structures, and high-frequency resonances resulted with almost complete loss of the frequencies above the resonance. In the type of reproducer shown in Fig. 1C the set screw is difficult to reach owing to the presence of the coil and pole pieces. Alternatives to the set screw were considered, but a more satisfactory solution appeared to be the location of the screw in the axis of rotation. In this position it can be made as long as desired and no effect of screw resonance has been

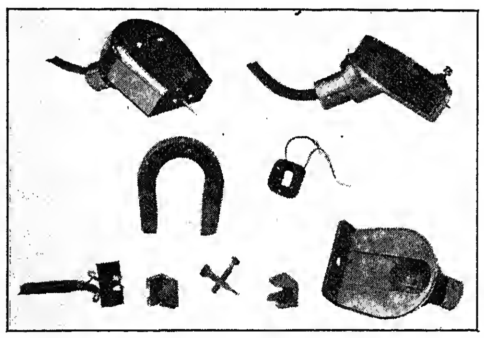

Fig. 6—Magnetic Phonograph Reproducer and Parts

observed. Placing the screw in the axis of rotation practically necessitates the half rocker rather than the full rocker construction, since the length of standard needles is such that the armature cannot extend far enough below the set screw to afford room for a coil and pole pieces.

Fig. 5 and 6 show the construction of a successful design of magnetic reproducer of the half rocker type. The armature is designed to have the smallest possible moment of inertia consistent with an adequate magnetic section and moderately large amplitude of movement of the upper end. In order that the axis of rotation may coincide with the screw and pivot axis at all frequencies, the armature is designed to have the center of gravity of the armature and needle coincide approximately with the pivot. The method of pivoting is unusual. In order that rotation might take place about the screw axis a journal type of bearing was desired, but all rubbing friction must be avoided in acoustic devices if distortion is to be obviated. Hence instead of having the shaft rotate within a journal with sliding friction, a film of rubber is interposed. This permits small rotation in either direction without friction but with a slight energy loss, more nearly resembling viscous damping, which is desirable. Objection might be made that such a pivoting system would permit translation as well as rotation. The objection may be answered in two ways. In the first place the yield of a sheet of rubber to direct compression is very slight. Rubber yields very readily in shear, and this permits rotation. It also yields easily in compression when it can expand freely in a lateral direction, but when a thin sheet of rubber completely fills the space between two surfaces whose dimensions are large compared with the thickness of the

rubber, compression becomes very difficult. In the second place a slight translation would do no appreciable harm, having the effect simply of shifting the center of rotation by a small amount, which does not materially reduce the output. Experience so far with this method of pivoting has shown it very satisfactory.

While the rubber packed journal provides a restoring force, whose magnitude depends on the shape of the post and thickness of the rubber, it is not sufficient to hold the armature in neutral position when a strong magnet is used. It was necessary to provide a supplementary elastic restoring force in the form of rubber plugs on either side of the "fish tail" or moving end of the armature. The rubber plugs provide not only the needed stiffness or stabilization but a very useful degree of damping.

For the purpose of making a simple analysis of the mechanical properties of the structure we may treat the arrangement as a flexible needle, a rigid rocking beam, with a spring tending to hold the rocker in normal position and an energy absorber in conjunction with the spring. Such a system is illustrated in Fig. 7. A certain motion is assumed to be imparted to the needle

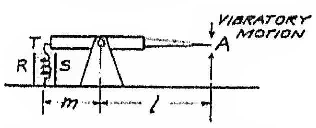

FIG. 7—REFERENCE FIGURE FOR DISCUSSION OF MECHANICAL BEHAVIOR

tip A, and we are concerned with the motion of the end T of the armature.

Let I = movement of inertia of the armature

n = stiffness of needle, that is the force at A required to deflect end of needle a given amount, (dynes per centimeter)

l = distance from pivot to needle point (centimeters)

m = distance from pivot to end T of armature

s = stiffness of restoring spring at T (dynes per centimeter)

R = resistance factor at T, (dynes per unit velocity)

f = frequency

ω = $2 \pi f$

A = amplitude of motion at needle tip

a = instantaneous deflection at the needle tip

X = amplitude of motion at end T

x = instantaneous deflection at point T

θ = angle of deflection of armature from mean direction.

θ is always small so that

$$\frac{x}{m} = \tan \theta = \sin \theta = \theta$$

P = maximum force applied at A

p = instantaneous force applied at A.

The driving moment is $p\, l$

The resisting moment is $m\,(s\, m\, \theta) + m \left(R\, m \dfrac{d\,\theta}{d\,t} \right)$

The difference between these two moments is expended in accelerating the armature

$$I \frac{d_2\ \theta}{d\,t^2} = p\,l - s\,m^2\,\theta - R\,m^2 \frac{d\,\theta}{d\,t} \tag{1}$$

The problem is most easily solved if we assume a sinusoidal motion at T and find the force and motion at A required to produce it.

Assume $x = X \cos 2\pi f t = X \cos \omega t$ (2)

$$\theta = \frac{x}{m} = \frac{X}{m} \cos \omega t \tag{3}$$

$$\frac{d\,\theta}{d\,t} = -\omega \frac{X}{m} \sin \omega t \tag{4}$$

$$\frac{d_2\,\theta}{d\,t^2} = -\omega^2 \frac{X}{m} \cos \omega t \tag{5}$$

Substituting (3), (4), and (5) in (1) gives

$$-I\,\omega^2 \frac{X}{m} \cos \omega t = p\,l - s\,m\,X \cos \omega t + R\,m\,\omega\,X \sin \omega t$$

$$p\,l = X \left(s\,m - I \frac{\omega^2}{m} \right) \cos \omega t - X\,R\,m\,\omega \sin \omega t \tag{6}$$

$$p = \frac{X}{l} \left\{ \left(s\,m - \frac{I\,\omega^2}{m} \right) \cos \omega t - R\,m\,\omega \sin \omega t \right\} \tag{7}$$

The deflection at the needle tip is the sum of that due to the tipping of the armature and that due to the bending of the needle.

$$a = l\,\theta + \frac{p}{n} \tag{8}$$

or from (3) and (8)

$$a = \frac{X}{m} l \cos \omega t + \frac{p}{n} \tag{9}$$

$$a = \frac{X}{m} l \cos \omega t + \frac{X}{n\,l} \left\{ \left(s\,m - \frac{I\,\omega^2}{m} \right) \cos \omega t - R\,m\,\omega \sin \omega t \right\}$$

$$a = X \left\{ \left(\frac{l}{m} + \frac{s\,m}{n\,l} - \frac{I\,\omega^2}{n\,l\,m} \right) \cos \omega t - \frac{R\,m\,\omega}{n\,l} \sin \omega t \right\} \tag{10}$$

Or considering amplitudes only

$$\frac{A}{X} = \sqrt{\left(\frac{l}{m} + \frac{s\,m}{n\,l} - \frac{I\,\omega^2}{n\,l\,m}\right)^2 + \left(\frac{R\,m\,\omega}{n\,l}\right)^2} \tag{11}$$

$$\frac{X}{A} = \frac{1}{\sqrt{\left(\frac{l}{m} + \frac{s\,m}{n\,l} - \frac{I\,\omega^2}{n\,l\,m}\right)^2 + \left(\frac{R\,m\,\omega}{n\,l}\right)^2}} \tag{12}$$

Equation (**12**) shows the manner in which the response will vary with frequency. For uniform response $\frac{X}{A}$ should be constant or independent of ω. As was stated in an earlier paragraph this condition will be realized (1) if the structure is rigid or (2) if the structure is what we might call a spring potentiometer. A rigid structure would mean making the needle stiffness n infinite. This would make equation (**12**) become

$$\frac{X}{A} = \frac{1}{\left(\sqrt{\frac{l^2}{m}}\right)^2} = \frac{m}{l} \tag{13}$$

or the motions at the two ends are proportional to the lever arm lengths.

Again if the inertia and damping are zero we obtain a constant ratio for $\frac{X}{A}$ for equation (**12**) becomes

$$\frac{X}{A} = \frac{1}{\frac{l}{m} + \frac{s\,m}{n\,l}} \tag{14}$$

in which all the factors are constants.

In equation (**12**) we see that at a certain frequency or value of ω, the factor $\frac{l}{m} + \frac{s}{n\,l} - \frac{I\,\omega^2}{n\,l\,m}$ will become zero. At this frequency $\frac{X}{A}$ will have a maximum value which is limited only by the damping. Setting $\frac{l}{m} - \frac{s}{n\,l} - \frac{I\,\omega^2}{n\,l\,m}$ equal to zero in equation (**12**) gives

$$\frac{X}{A} = \frac{1}{\frac{R\,m\,\omega}{n\,l}} = \frac{n\,l}{R\,m\,\omega} \tag{15}$$

In general damping does not play an important part except near the resonant frequency. The inertia becomes a minor factor when the frequency is well below that at which resonance occurs, so that in the lower part of the frequency range the ratio $\frac{X}{A}$ approximates the constant value shown in equation (**14**). The construction of a reproducer in which distortion is reduced to a negligible quantity, therefore depends on making the resonance occur at a frequency so high that the most important part of the acoustic range is included below the resonance. It is furthermore necessary that there be sufficient damping so that the response at the resonance frequency is not excessive. It is to be noted that the resonance frequency is determined by the inertia of the armature and the restoring force not of the spring or cushions alone, but the combined stiffness of the springs and the needle. The natural frequency of the armature with the needle free has practically nothing to do with the response characteristic of the reproducer. The resonance corresponds to the natural frequency of the armature when the needle tip is held stationary. The action at resonance might be described as a whipping, such that a small movement at the needle tip causes large motion of the armature. Below resonance we may regard the vibrations as entirely forced by the cut in the record both as to amplitude and frequency.

To obtain a high resonance frequency, the first requisite is to make the moment of inertia of the armature small. At the same time the moving end of the armature must be far enough from the center of rotation to vibrate with considerable amplitude, and from the standpoint of magnetic design the cross-section of the armature must be sufficient to have low reluctance and to avoid any possibility of saturation. In practise it was found that the last mentioned conditions were met when the armature was made heavy enough for mechanical sturdiness and long enough to provide reasonable winding space. Special care has been taken to minimize the mass of those parts of the armature which have greatest motion, metal which is close to the axis of rotation having little influence on the moment of inertia.

The second requisite for high natural frequency is stiffness either in the spring or the needle or both. Reference to equation (**14**) which throughout most of the frequency range is a measure of the response, shows that if we increase the spring stiffness s, we decrease the sensitivity, while increasing n, the needle stiffness increases sensitivity up to a certain limit. It might seem, therefore, that the stiffest needle obtainable should be used, and the spring stiffness should be only what is required to hold the armature in neutral position. But the effect on sensitivity is small so long as the fraction $\frac{s\,m}{n\,l}$ is small compared with $\frac{l}{m}$, and damping is best when a "soft" needle is used, for the following reason. The needle is a highly resilient spring, whereas the spring S which in the present design consists in a pair of rubber plugs, has a large damping factor. In fact the damping R, and stiffness s, go together. With a given value of s

and R, the stiffer the needle the greater the resonance response, as shown in equation (**15**). Hence we work with the largest ratio of cushion stiffness to needle stiffness which we can use without serious loss of sensitivity. A factor which helps make it possible to get the desired damping without excessive stiffness at s, is the presence of the magnet, which tends to pull the armature away from neutral position and thereby

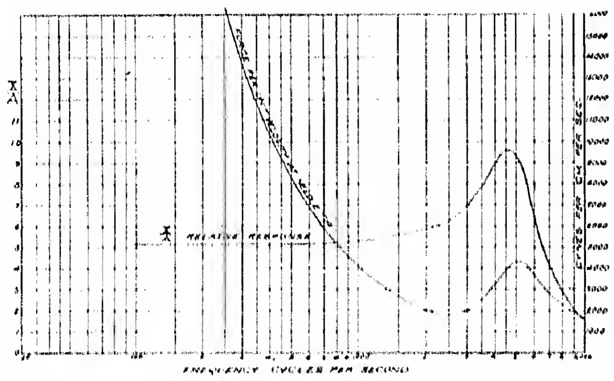

FIG. 8—CALCULATED CHARACTERISTICS OF MAGNETIC REPRODUCER

reduces the net stiffness to considerably less than the value it has when the magnet is removed.

Measurements on a sample magnetic reproducer gave the following values of the principal constants.

Mass of armature with Victor medium needle 1.9 grams.

Moment of inertia of armature and needle $I = 0.28$ gm. cm.^{2}

Length, center of rotation to moving end of armature, $m = 1.1$ cm.

Length, center of rotation to tip of needle (Victor medium) $l = 1.5$ cm.

Stiffness of armature mounting (assumed concentrated at end) $s = 70{,}000{,}000$ dynes per cm.

Same with magnet removed. 90,000,000 dynes per cm.

Stiffness of needle (Victor medium, clamped for ⅜ in.) $n = 86{,}000{,}000$ dynes per cm.

Damping factor as calculated from observed increase in response at resonance, $R = 3720$ dynes per cm. per sec.

Fig. 8 shows characteristics calculated from the above constants. It will be noticed that the required driving force at the needle tip has a minimum value at 2800 cycles. This is the natural frequency of the armature when the needle is free. It is also to be observed that the armature resonance at 5000 cycles is accompanied by an increase in the force reaction. Hence damping to keep down the resonance not only improves the response characteristic, but reduces the wear on the record.

Fig. 9 shows response curves of several factory samples of reproducers, taken by means of an oscillograph. The oscillograph vibrator is supplied from the output stage of a resistance coupled amplifier. The film is run slowly and the width of the envelope of the vibrations is a measure of the voltage applied by the reproducer to the grid of the first tube. The record used for this test is one cut by a special process so as to give an amplitude of cut varying inversely as the frequency. In other words a constant velocity cut is used. The approximate frequencies are indicated on each film. A slight increase in voltage is noticed toward the upper end of the frequency scale, followed by a drop to almost zero, for in all cases the output falls off very rapidly above the resonance frequency.

Scratch Control Circuit. Any exaggeration of the high frequencies produces a disagreeable increase in "surface noise" or "scratch." It has appeared desirable in fact to partially suppress the higher frequencies in order to reduce scratch. This has been accomplished by connecting a coil and condenser in series across the reproducer winding.[7] This shunt circuit tunes at about 4500 cycles but has a decided effect at 3500 cycles and above. The width of the frequency band affected may be controlled by varying the ratio of capacity to inductance, while the degree of suppression for the frequency at which the reactance is minimum, is determined by the resistance of the coil. The suppression of high frequencies is at the cost of some articulation in speech but on the whole gives a more pleasing result, particularly with musical numbers.

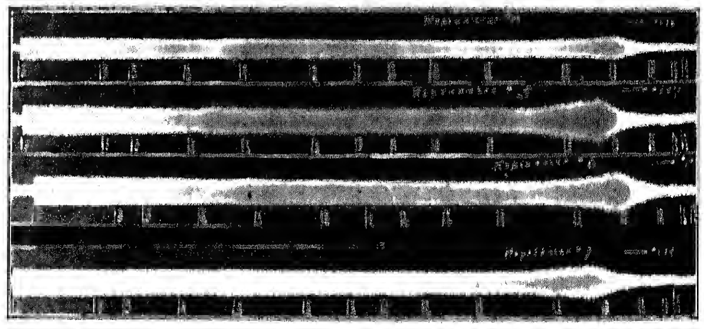

FIG. 9 RELATION BETWEEN VOLTAGE AND FREQUENCY FOR MAGNETIC REPRODUCERS

Tone Arm Vibrations. The foregoing analysis of the action of the reproducer is based on the assumption that the device as a whole remains stationary with respect to the axis of the groove in the record. This condition, however, does not necessarily obtain. The net stiffness at the needle tip which is $1/(l^2/m^2\, s + 1/n)$ is sufficient to resonate with the mass of the entire reproducer at a frequency of the order of 150 cycles. Since the reproducer is fairly rigidly mounted on the tone arm, the inertia, flexibility, and

7. The "scratch control" circuit which is being used was a contribution of Mr. Julius Weinberger of the Technical and Test Department of the Radio Corporation of America. He also built the first magnetic reproducer of the bottom-pivoted half rocker type. This model which showed excellent characteristics, served as the basis for the design described in this paper.

mechanical damping in the latter play a part in this type of resonance. Flimsy construction of the tone arm or its mounting gives rise to an irregularity in the response at low frequency, which while not an extreme resonance nor especially noticeable in listening is nevertheless a defect. Rigid construction and especially some energy loss at the pivot on which the arm swings, appear to be a practically complete cure for low frequency resonance of the type just described, and with such a satisfactory carriage the response becomes practically uniform from below 100 cycles to above 4000 cycles.

ACKNOWLEDGMENT

The practical success of any device depends in large measure on the engineering skill with which it is placed on a manufacturing basis. In the present case some unusual problems presented themselves and much credit is due Messrs. F. C. Barton and J. E. Albright of the Radio Manufacturing Department, of the General Electric Co., and to Mr. R. Hillner, for the solution of the manufacturing problems and for turning out a final product equal in quality to the original laboratory samples and better in regard to output and reliability. Early experiments by Mr. Barton on magnetic pick-ups showed the possibilities of the system, and interested others in the development.

Acknowledgment should also be made of the important contributions of Mr. Julius Weinberger of the Technical and Test Department of the Radio Corporation of America.[7]

Discussion

C R. Hanna: In the paper by Mr. Kellogg no mention has been made of factors which determine the sensitivity of the pickup device other than that mass has something to do with it.

This statement is made: "The foregoing comparison of magnetic systems does not take into account the possible power output of the winding, nor is the elastic stiffness required to hold the armature in its mean position allowed to weigh in the choice. The comparison is wholly from the standpoint of obtaining the maximum open-circuit voltage with the minimum effective inertia of moving parts."

This discussion has to do with the factors which affect the sensitivity. The first of these is elastic stiffness which is not taken into account in the paper. In Fig. 8 of the paper, the curve given for the reaction force on the record against frequency, shows that the pickup device requires greater driving force in the low range of frequencies for a given velocity, and therefore, may cause excessive wear on the record. The stiffer the restoring member the steeper this curve will be. The stiffness of the restoring member, which in the design described by Mr. Kellogg is principally in the upper two rubber plugs, must be sufficiently great to prevent the armature from being pulled over to one pole or the other. The presence of the magnetic poles thus produces an effect which is known as magnetic reduction of stiffness and this reduction of stiffness must never be greater than the mechanical stiffness of the mechanical restoring member. In manufacture, it is never possible for the magnetic reduction of stiffness to be greater than some 50 per cent of the mechanical stiffness, leaving about 50 per cent as net stiffness. To prevent excessive wear to the record the net stiffness must be small, and since the magnetic reduction of stiffness bears a constant ratio to the mechanical stiffness, the magnetic stiffness cannot be greater than a certain amount. This necessitates either a weak magnet, a long air-gap, or fairly small pole faces, all of which make for low senstivity.

The other factor that weighs in sensitivity is the inductance. If more turns are wound on the coil, or a higher-ratio step-up transformer is used, to get greater output voltage, the inductive impedance of the device may become too high for the circuit into which it is to operate; namely, the grid of the vacuum-tube amplifier. Thus, the effective inductance of the device has a definite upper limit.

Now, as a general proposition, it can be shown that if magnetic saturation and leakage are negligible, the sensitivity expressed in volts per unit velocity at the needle is dependent upon two factors only: (1) the magnetic reduction of stiffness, which is limited because of wear on the record at low frequencies; and (2) the inductance of the device, which is limited because of the impedance of the vacuum tube into which the device is to operate. The relation[2] is Volts/(cm./sec.) $= \sqrt{10^{-7} \times \text{Inductance} \times \text{Magnetic Stiffness}}$. When these two factors are held constant, all of the arrangements which were shown in the paper will have the same sensitivity characteristic, provided magnetic saturation or magnetic leakage do not come into play.

2. C. R. Hanna, Design of Telephone Receivers for Loud-Speaking Purposes, *Proceedings*, I. R. E., August 1925. The relation given in this paper is for the force factor and must be divided by 10^7 to obtain generated voltage per unit velocity. While the proof of the relation is given for a particular structure, it can be shown that it applies to all devices in which the inductance varies inversely with a linear function of the displacement of the moving iron member.

And so the advantage of one construction over another, magnetically, in any case will be due to less leakage or less saturation, or both. Of the various arrangements having low saturation and leakage, the above relation shows that the one which is most suitable for mechanical considerations may be chosen without sacrifice of sensitivity.

E. W. Kellogg: Mr. Hanna has called attention to the fact that in making my choice from the numerous possible magnetic arrangements, I have limited my consideration to certain criteria; namely, securing the maximum volts per turn for a given magnitude of stored energy in the inertia of the vibrating armature. He introduces a different point of view, in which the stiffness of the armature mounting is to be limited in order not to cause excessive wear on the record, and he reaches the interesting conclusion that if well designed, almost any of the magnetic systems is as good as any other. This conclusion is itself a vindication of the point of view adopted in the paper. With armature stiffness as the controlling factor, there is no choice; but when we take small inertia as the desideratum, the choice is narrowed down to one or two arrangements. The reduction of inertia of the vibrating parts is desirable from the standpoint of wear on records, but is especially important for high-quality reproduction. The lighter the moving parts, the higher will be the frequency at which whip resonance occurs, and therefore the greater the range of frequencies which can be reproduced. The fact that the force on the needle tip is greater at low frequency where stiffness is the controlling factor than at high frequency where inertia predominates, may be taken as an indication that the effort to keep the inertia low was successful. The stiffness is not materially greater than that of mechanical reproducing systems, and if experience shows that greater flexibility is important, it will have to be secured, as Mr. Hanna's analysis shows, at the cost of lower sensitivity. In this connection I should like to commend Mr. Hanna's I. R. E. paper, for it is instructive and interesting. But the case considered there is a loud-speaker design and the factor which is of primary importance in one problem is not necessarily so in the other. The fundamental difference is that in the loud-speaker drive the current supplied results in a certain force being applied to the diaphragm and the amplitude is determined by the ease of movement of the diaphragm, while in the phonograph reproducer, the amplitude is practically fixed by the groove in the record.

The question might be raised why voltage per turn instead of power output was taken as the measure of efficiency of the magnetic arrangement. When the reproducer was first designed, it was expected that it would be connected directly to the grid of a tube, without a transformer. In this case, the minimum size of wire and available winding space being practically fixed, the useful output would be measured in terms of the voltage per turn developed by a given needle, velocity. If the reproducer is used with a transformer, the possible power or volt-ampere output appears to be a more logical basis for comparison of different structures. I should like to add a brief discussion of this case.

If the transformer has a step-up ratio N, and if the capacity to ground of the tube grid and wiring is C, the effect of the transformer is to load the reproducer winding with an effective capacity $N^2 C$. But this must not resonate with the winding inductance within the working range of frequencies, for such resonance would impair quality of reproduction. The lower the winding inductance the greater the step-up ratio which may be employed. Hence, if we can lower the inductance by raising the reluctance of the magnetic circuit without reducing the flux change which results through the winding from a given needle movement, we make it possible to use a higher step-up ratio and apply more voltage to the grid. A consideration of the several magnetic systems illustrated in my Fig. 4 will show that we have no reason for revising our choice of double acting or push-pull systems in preference to single acting systems, or of rocking rather than translation type armature.

There is, however, a different aspect to the comparison of the half-rocker and full-rocker armatures. It was argued in the paper that if the reluctance of the magnetic joint at the pivot of the half-rocker is kept low, the voltage developed would be nearly as much as with a full rocker. For simplicity, let us take the ideal case in which the pivot point reluctance is zero. The voltage per turn will be the same as with a full rocker, while the inductance would be twice that of the full rocker device. This would necessitate reducing the transformer step-up in the ratio $1/\sqrt{2}$ or 0.707, and the voltage at the grid would be reduced in the same ratio, which corresponds to cutting the power in half.

Were it not for practical difficulties having to do with clamping the needle, the full-rocker armature would perhaps have been chosen. But these difficulties were serious, and the advantage of the full rocker is not so great as the two to one power ratio would make it appear. In the first place, the power ratio is based upon the assumption that both ends of the full-rocker move as much as the one moving end of the half-rocker. This would mean more metal to be moved, and if the whip frequency is to be kept high, there would have to be a compensating reduction in amplitude. Again the full rocker, if proportioned to give twice the power output of the half rocker, would require twice as stiff a mounting to stabilize the armature in the air-gaps, and this, as Mr. Hanna has pointed out, is objectionable from the standpoint of record wear. By the time these factors are compensated by changing the ratio of armature to needle movement, practically all the advantage of the full rocker armature has disappeared.

Television

BY HERBERT E. IVES*

Synopsis.—*The chief problems presented in the accomplishment of television are discussed. These are, the resolution of the scene into a series of electrical signals of adequate intensity for transmission; the provision of a transmission channel capable of transmitting a wide band of frequencies without distortion; means for utilizing the transmitted signals to re-create the image in a form suitable for viewing by one or more observers; arrangements for the accurate synchronization of the apparatus at the two ends of the transmission channel.*

* * * * *

Introduction

THIS paper is to serve as an introduction to the group of papers following, which describe the apparatus and methods used in the recent experimental demonstration of television over communication channels of the Bell System. In that demonstration television was shown both by wire and by radio. The wire demonstration consisted in the transmission of images from Washington, D. C. to the auditorium of the Bell Telephone Laboratories in New York, a distance of over 250 miles by wire. In the radio demonstration, images were transmitted from the Bell Laboratories experimental station at Whippany, New Jersey, to New York City, a distance of 22 miles. Reception was by two forms of apparatus. In one, a small image approximately 2 in. by 2½ in. was produced, suitable for viewing by a single person, in the other a large image, approximately 2 ft. by 2½ ft., was produced, for viewing by an audience of considerable size. The smaller form of apparatus was primarily intended as an adjunct to the telephone, and by its means individuals in New York were enabled to see their friends in Washington with whom they carried on telephone conversations. The larger form of receiving apparatus was designed to serve as a visual adjunct to a public address system. Images of speakers in Washington addressing remarks intended for an entire audience, and of singers and other entertainers at Whippany, were seen by its use, simultaneously with the reproduction of their voices by loud speaking equipment.

Characteristic Problems of Television

The problem of television in its broad outlines is that of converting light signals into electrical signals, transmitting these signals to a distance, and then converting the electrical signals back into light signals. Given means for accomplishing these three essential tasks, the problem becomes that of developing these means to the requisite degree of sensitiveness, speed, efficiency, and accuracy, in order to re-create a changing scene at a distant point, without appreciable lapse of time, in a form satisfactory to the eye.

A convenient starting point for the discussion of television is the human eye itself. In this an image is formed upon the retina, a sensitive screen, consisting of a multitude of individual light-sensitive elements. Each of these elements is the termination of a nerve fibre which goes directly to the brain, the entire group of many million fibres constituting the optic nerve. A theoretically possible television system could be made by copying the eye. Thus a large number of photosensitive elements could be connected each with an individual transmission channel leading to a distant point, and signals could be sent simultaneously from each of the sensitive elements to be simultaneously used for the re-creation of the image at the distant point. The number of wires or other communication channels demanded in a television system of this sort would be impractically large. For practical purposes, reduction of the number of transmission channels is made possible by the fact that, while in vision all parts of the image on the retina are simultaneously and continuously acting to send nerve impulses, the inertia of the visual system is such that a sensation of continuity is obtained from discontinuous signals, provided these succeed each other rapidly enough. Due to the phenomenon of persistence of vision, it is immaterial to the eye whether the whole view be presented simultaneously or whether its various elements be viewed in succession, provided the entire image be traversed in a sufficiently brief interval, which for purposes of discussion may be taken as 1/16th of a second or less[1]. We thus have available in television the same artifice which is used in the much less exacting problem of transmission of pictures over a telephone line, that is, of *scanning*, or running over the elements of the image in sequence, instead of endeavoring to transmit all of the elementary signals simultaneously. The development of a television system therefore necessitates, at an early stage, the design of some scanning system by which the image to be transmitted may be broken up into sequences of signals. In the simplest case, where one transmission channel is to be used, the whole image will be resolved into a single series of signals; if more than one transmission channel is to be utilized, the resolution may, by parallel scanning schemes, or their equivalent, be broken up into several series for simultaneous transmission.

*Bell Telephone Laboratories, Incorporated, New York, N. Y.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

1. This figure of 1/16th of a second, commonly quoted in discussions of this sort, is a convenient one, although the frequency of image repetition necessary to extinguish "flicker" is actually proportional to the logarithm of the field brightness. A somewhat higher rate of image repetition was used in the final television apparatus.

Like the eye, an artificial television system must have some light-sensitive element or elements by means of which the light from the object shall produce signals of the sort which can be transmitted by the transmission system to be used. For a television system to operate over electrical transmission lines this means some photoelectric device. It is obvious that this photoelectric device must be extremely rapid in its response, since the number of elements of any image to be transmitted must be some large multiple of the fundamental image repetition frequency, that is 16 per second. The response should, of course, be proportional to the intensity of the light, and finally, the device must be sufficiently sensitive so that it will give an electrical signal of manageable size with the amount of light available through the scanning system. This latter requirement, that of sensitiveness, is one which, it was realized from studies made with our earlier apparatus for the transmission of still pictures over wires[2], would be extremely difficult to meet. In the picture transmission system a very intense beam of light from a small aperture is projected through a transparent film and on to a photoelectric cell. In practical television, the system must be arranged to handle light reflected from a natural object, under an illumination which would not be harmful or uncomfortable to a human being. Actual experiment showed that the greatest amount of light which could be collected from an image, formed by a large aperture photographic lens on the small scanning aperture of the picture transmission apparatus was less by a factor of several thousand times than the light projected through it for still picture transmission purposes. Assuming the same kind of photoelectric cell to be used, the additional amplification required over that used in the picture transmission system, taking into account also the higher speed of response demanded, would bring us at once into the region where amplifier tube noise and other sources of interference would seriously affect the result. This indicated clearly that some more efficient method of gathering light from the object than the commonly assumed one of image formation by a lens was required, unless some much more sensitive type of photoelectric cell should be found.

Assuming that means could be developed for producing an electrical signal proportional to the intensity of the light, of sufficient quickness to follow a rapid scanning device, and of sufficient strength either as directly delivered from a photosensitive device or as amplified, the next problem is that of its transmission over an electrical communication system. We may quickly arrive at an understanding of certain of the transmission problems by reviewing the requirements for the transmission of photographs. In the system of still picture transmission now in use by the American Telephone & Telegraph Company, a picture 5 in. by 7 in. in size, divided into the equivalent of 10,000 elements per square inch or 350,000 elements, is transmitted in approximately seven minutes. This requires the transmission of a frequency band of about 400 cycles per second on each side of the carrier frequency. If we plan, in the transmission of television, to transmit images of the same fineness of grain, it would mean that what is now transmitted in seven minutes would have to be transmitted in a 16th of a second, which in turn means that the transmission frequency range would have to be nearly 7000 times as great. That is, a band approximately 3,000,000 cycles wide would be required. Bearing in mind that wire circuits are ordinarily not designed to utilize frequencies higher than 40,000 cycles per second, and that with radio systems uniform transmission of wide signal bands becomes extremely difficult, it is seen at once that either an image of considerably less detail than that which we have been considering must suffice, or else some means for splitting up the image so that it may be sent by a large number of channels is indicated.

A further theoretical requirement must also be given consideration. This is that the complete television signal will consist of all frequencies up to the highest above discussed, and down to zero, that is, an essential part of the signal is the direct current component, furnished by those parts of the scene which do not change. The problem of handling the very low frequency components, presents difficulties both in the vacuum tube amplifier system adjacent to the photosensitive device, and in ordinarily available transmission channels.

In any case certain fundamental transmission requirements must be met. These are that the attenuation of the signals must be uniform over the whole frequency range and that the speed of transmission of all frequencies must be the same. Also, as in the transmission of sound signals, the amount of interference or noise must be kept down sufficiently not to impair the quality of the signal or picture.

Assuming the undistorted transmission of the signals to a distant point, the next fundamental problem of television is the reconstruction of the image, or the translation of the electrical signal back into light of varying intensity. Just as at the sending end we have seen that the production of a useful electrical signal with the amount of light available from a naturally illuminated object is a major problem, so at the receiving end the converse problem, that of securing an adequately bright light from the electrical signal, presents great difficulty. The nature of the problem may be understood by assuming that it is to be done by projecting the received image on a screen similar to an optical lantern projection screen. If the spot of light which is to build up this image scans the whole area in the same way that the object is scanned, we find that the amount of light which can be concentrated into a

2. "Transmission of Pictures over Telephone Lines," Ives, Horton, Parker, and Clark. *Bell System Technical Journal*, Vol. IV, No. 2, April, 1925.

small elementary spot will, when distributed by the scanning operation over the whole screen, reduce the brightness of the screen in the ratio of the relative areas of the elementary spot and the whole screen. The amount of this reduction will, of course, depend upon the number of elements into which the picture is divided, but will in any event be a factor of several thousand times. It is doubtful whether any light source exists of sufficient intensity such that an image projected by it can be spread out by a scanning operation over a large screen and give an average screen brightness which would be at all adequate. It is possible to imagine optical systems by which such a thing as the crater of an arc could be projected upon the screen, but the motion of this image and its variation in intensity would involve the extremely rapid motion of lenses, mirrors, and apertures of a size such as to render the operation mechanically impracticable. It appears from these considerations, that the only promising means of reconstructing the image would be those in which a light source, whose intensity can be controlled with great rapidity, is directly viewed.

Another element of a television system upon whose solution success depends as much as any other is that of synchronization; the reconstruction of the image, postulated in the last paragraph, is only possible if the reconstructed elements fall in exactly the right positions at the right times, to correspond with the signals as generated at the analyzing end. The criterion for satisfactory synchronization will be expressed in terms of variation from identity of speed by figures which will depend on the fineness of grain of the image which it is planned to send. No element of the image must, of course, be out of place by a considerable fraction of the size of the element.

General Outline of Means Employed in the Present Television System

It has been pointed out above that if the goal which we set in television is the transmission of extended scenes, with a large amount of detail and hence made up of an exceedingly large number of elementary areas, we meet with the necessity for transmission channels of a character which are not now available. In the present development it was decided at the start to restrict our experiments to a size and grain of picture which, if the scanning and re-creating means were developed, would be capable of transmission over practical transmission channels, either wire or radio. This restriction fortunately leaves us with the possibility of meeting what was felt to be the typical problem of a Telephone Company, namely the transmission of a human face in a television system used as an adjunct to a telephone system. Taking as a criterion of acceptable quality, reproduction by the halftone engraving process, it is known that the human face can be satisfactorily reproduced by a 50 line screen. Assuming equal definition in both directions, 50 lines means 2500 elementary areas in all; 2500 elements transmitted in 1/16 second is 40,000 elements per second. The frequency range necessary to transmit this number of elements per second with a fidelity satisfactory for television cannot be calculated with assurance in advance. An approximate value can however be arrived at from a study of the results obtained in still picture transmission. In pictures transmitted by the system already referred to, individual faces contained in a square space ½ inch on a side are quite recognizable[3]. Taking the ratio of this area to the area of the whole picture, and using the frequency range figure already deduced, for a complete 5 in. by 7 in. picture, it appears that a band of 20,000 cycles would be sufficient to transmit such an image in 1/16 second[4]. These considerations led to the choice of a 50 line (2500 element) image as one which would be both satisfactory as to detail rendering, for our purposes, and as calling for frequency transmission requirements sufficiently low to give a good margin of safety in existing single communication channels.

As a method of scanning, the method which is probably mechanically simplest, namely that of rotating disks with spirally arranged holes, proposed by Plotnow[5] in 1884, was chosen. In accordance with the choice of grain above indicated, the disks were perforated with 50 apertures.

For the second element of the problem, the light-sensitive means, the alkali metal photoelectric cell was chosen as possessing the qualities of proportionality of response and quickness of reaction. The currents produced by it are at best quite small, but they lend themselves to the process of amplification by the three-electrode vacuum tube amplifier.

The problem of securing a large enough signal, which is intimately associated with that of securing enough light from the object, was, in our development work, postponed in the earlier stages, our first experimental work having been done by concentrating light through photographic transparencies[6]. The solution of the problem of securing adequate light was subsequently attained by reversing the light path and projecting a narrow beam of light through the scanning disk upon the object. By this means only the element of the object which was being scanned was illuminated at any one time, thereby reducing the average illumination enormously, and the problem of increasing the signal strength could be attacked by increasing the amount

3. c. f. Fig. 18 of the paper referred to (Reference 2).

4. A factor which this analogy does not cover is that if the image is moving so that it falls on several discrete scanning elements in rapid succession a very material apparent increase in the fineness of the image structure results. This effect is similar to that by which the relatively coarse grained individual images in a motion picture film fuse to give smooth appearing pictures.

5. Plotnow, D. R. P. 30105, 6.1, 1884.

6. As one step in the development work moving picture film, projected by a commercial projector in synchronism with the scanning disks, was successfully transmitted.

of photo-sensitive surface as well as by increasing the brightness of the scanning light[7].

The problem of amplifying the photoelectric currents to sufficient value for transmission was solved by a practical compromise which at the same time met one of the transmission difficulties. This compromise consisted in amplifying and transmitting only the fluctuating or alternating current components of the signal, leaving the direct current component, which determines the general tone value of the image, for empirical reintroduction at the receiving end. By this scheme, stable amplifier constructions were made available, and the transmission channels, particularly the wire channels, could be utilized in their normal working form.

At the receiving end, the problem of securing a sufficiently bright image was solved, as indicated earlier, by the use of self-luminous surfaces of much higher intrinsic brightness than it is possible to secure by illumination of a surface by any light source which can be rapidly controlled as to its intensity. The self-luminous surfaces employed were glow lamps containing neon gas, the brightness of which changes with sufficient rapidity to follow the incoming signals.

The problem of synchronization was postponed in our earlier development work by mounting the scanning and receiving disks upon the same axle. It was later solved for the demonstration apparatus by the utilization of synchronous motors controlled by two frequencies, a low frequency, that of the image repetition period and a high frequency, chosen of such a value that the fraction of the cycle through which hunting occurred amounted in angular displacement to less than half the angular extent of a single disk aperture. The synchronization control therefore called for the transmission of additional currents for synchronization purposes over and above the picture current.

In order to transmit and synchronize the image signals it is necessary to transmit three different frequency bands, one for the image, and two for the high and low frequency synchronization controls. In the demonstration of April 7, 1927, the images were sent in the wire demonstration over a high quality open wire line. The synchronization control was sent over two separate carrier channels of a second telephone line. In addition to these lines, another line was used for conveying the telephone conversation. In the radio demonstration two different wavelengths were used respectively for the image signals and for the synchronization signals which were, as in the wire demonstration, carried on two different carrier frequencies. A third channel was used for the voice. In the case of both wire and radio transmission, it is quite possible to put all of the different signals upon the same transmission channel, using different carrier frequencies.

It will aid toward a clear understanding of the reasons for the success of the system of television described in the following papers if we summarize at this point the chief novel features to which that success is due. They may be listed as follows:

1. Choice of image size and structure such that the resultant signals fall within the transmission frequency range of available transmission channels.[8]
2. Scanning by means of a projected moving beam of light.
3. Transmission only of alternating current components of image.
4. Use of self-luminous surfaces of high intrinsic brilliancy for re-construction of the image.
5. High frequency synchronization.

Applications and Future Developments

It is not easy at this early date to predict with any confidence what will be the first or the chief uses for television, or the exact lines that future development may take. It must be clearly understood that television will always be a more expensive service than telephony, for the fundamental reason that it demands many times the transmission channel capacity necessary for voice transmission. This expense will inevitably increase in proportion to the size and quality of the transmitted image.

The kinds of service which are naturally thought of upon consideration of the services now rendered in connection with sound transmission are: first, service from individual to individual, parallel in character to telephone service, and as an adjunct thereto; second, public address service, by which the face of a speaker at a distant point could be viewed by an audience while his voice was transmitted by loud speaker; third, the broadcasting of scenic events of public interest, such as athletic contests, theatrical performances, and the like.

The first two types of service just mentioned lie within the range of physical practicability, with apparatus of the general type already developed. The third type, because of the uncontrolled conditions of illumination, and the much finer picture structure which would be necessary for satisfactory results, will require a very considerable advance in the sensitiveness and the efficiency of the apparatus, to say nothing of the greatly increased transmission facilities. For all three types of service, wire or radio transmission

7. A still further advantage is obtained by limiting the scanning light to the region of the spectrum to which the photoelectric cells are sensitive (blue and violet). This is unnecessary where one way transmission only is used but is of value where in two way transmission a transmitted image is to be viewed by a person being scanned.

8. As the succeeding papers show, the margin between the frequency range required by the scanning apparatus and that which could be made available was quite liberal. It appears in the light of our experience that apparatus with 60 or 70 scanning holes instead of 50 might be used with the transmission facilities which were at our disposal.

channels could be utilized, for while the problems incident to securing distortionless transmission over wide frequency bands, or multiple transmission channels, are different in detail in the two cases, they appear to be equally capable of solution by either means. However, the very serious degradation of image quality produced by the fading phenomena characteristic of radio indicates the practical restriction of radio television to fields where the much more reliable wire facilities are not available.

The Production and Utilization of Television Signals

BY FRANK GRAY*, J. W. HORTON*, and R. C. MATHES*

Non-Member — Member, A. I. E. E. — Associate, A. I. E. E.

Synopsis.—*The design of a television system, once the fundamental principles are understood, involves a detailed consideration of the methods by which the several important functions are to be performed.*

(1) *In the present system the initial signal wave is obtained by sweeping a spot of light over the subject in parallel lines completely scanning it once every 18th of a second. The light reflected is collected by large photoelectric cells which control the transmitted current. At the receiving station the picture current controls the brightness of a neon lamp from which the received image is built up by means of a small aperture moving in synchronism with the spot of light at the transmitting station. For presentation to a large audience television images may be produced by a neon lamp in the form of a grid having a large number of separate electrodes. A high frequency excitation controlled by the picture current is distributed to the successive electrodes in synchronism with the spot of light at the transmitting station.*

(2) *Space and time variations in the reflecting power of the subject are translated into time variations in signal strength. For design purposes these time variations are represented by component frequencies, a minimum band of which must be properly transmitted to insure an adequate reproduction of the image. Within this band there must be maintained a certain degree of uniformity in the efficiency of transmission of the separate components. Also, their phases must not be permitted to shift unduly in relation to each other.*

(3) *The design of the terminal amplifiers is based on the quantitatively determined characteristics of the photoelectric cells and of the neon lamps as well as on the limits imposed by the transmission study and by the characteristics of available transmission media, whether telephone line or radio system. The circuits employed at the transmitting station furnish an amplification such that the power delivered to the transmission medium is 10^{15} times the power received from the photoelectric cells.*

SECTION I

Apparatus for the Analysis and Synthesis of the Image

THE introductory paper to this series of articles on television explained principles along which any television system must operate to transmit an image over a single pair of wires or other channel of communication. As the first step in such a transmission, the space variations in brightness from point to point in the view must be translated into time variations in an electrical current that can be sent over the channel of communication. This translation may be accomplished by a scanning process that operates on the view to produce the same effect as if the view were cut up into a single long strip and passed rapidly in front of a light-sensitive cell to generate an electrical current varying with the brightness along the strip. To eliminate flicker in the reconstructed image and also to follow moving subjects in a view, the scanning process must be repeated and a new picture transmitted at least every sixteenth of a second.

Many purely theoretical methods could be, and have been, devised to accomplish such a scanning process and to translate a view into electrical currents or signals. Unfortunately, however, a practical system of television must operate with materials and conditions as they exist, and these practical limitations constitute the serious problems of television.

The high speeds and relatively large amplitudes with which any television scanning mechanism must move, and the necessity for synchronizing the transmitting and receiving apparatus lead to the use of synchronously rotating machines as apparently the only practical solution of the scanning and receiving problems. Consequently, the present television system has been designed to operate with continuously rotating mechanical parts.

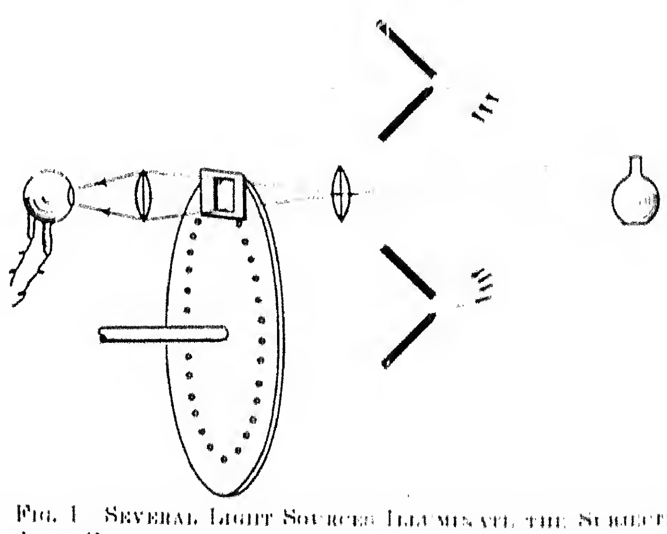

FIG. 1 SEVERAL LIGHT SOURCES ILLUMINATE THE SUBJECT; A LENS FORMS AN IMAGE WHICH IS SCANNED BY A SPIRAL OF APERTURES, THROUGH WHICH THE LIGHT FALLS ON A SINGLE PHOTOELECTRIC CELL

The efficiency that must be secured in the optical part of any scanning method is fixed by the three following factors—the amount of picture detail that is to be transmitted, the efficiency of the light sensitive cell, and the practical limit to amplifier systems. The first of

*All of Bell Telephone Laboratories, Incorporated, New York, N. Y.

Presented at the Summer Convention of the A. I. E. E. Detroit, Mich., June 20-24, 1927.

these factors decides the area from which light can be collected at any one instant. In the present case this was fixed in an initial survey of the entire television problem when it was decided to confine the first attempt to the transmission of pictures as if they were made up of 2500 small elemental areas; that is, to scan the view in a series of fifty parallel lines. The second factor is determined by the sensitivity of the potassium

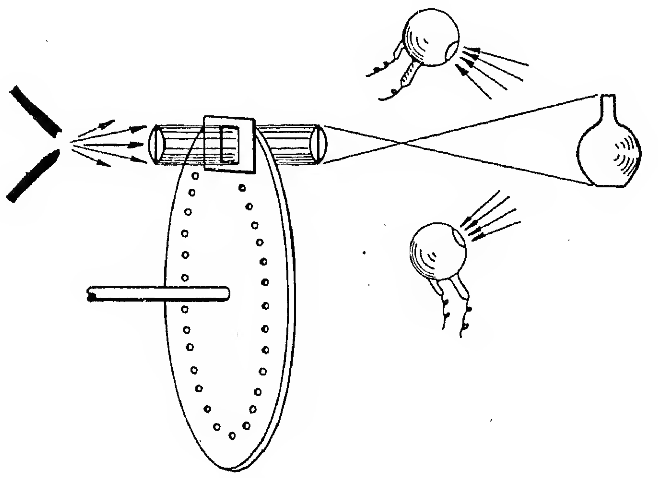

Fig. 2—Light from a Single Source is Projected as a Small Moving Spot on the Subject; the Reflected Light is Received by Several Photoelectric Cells

hydride photoelectric cell. This cell is, at the present time, the most efficient light-sensitive cell that can follow the rapid variations in light intensity without a time lag. The third factor, the limitation of amplifier systems, results from the extraneous currents that are present in metallic conductors and amplifier tubes. The thermal agitation of the electrons in any input resistance generates such currents; and rapid variations in the number of electrons emitted from the hot filament of an amplifier tube also generate disturbing voltages. For successful amplification, the initial photoelectric current must be considerably larger than these extraneous currents. Consequently, the optical arrangement must be such that at any one instant it collects enough light from an elemental area of the view to generate this minimum permissible output current from the photoelectric cell.

The operation and advantages of the scanning method actually used in the present process for transmitting television images may be better understood by first considering a simple and analogous method illustrated by Fig. 1. The subject is illuminated by lights placed in front of it as shown. A lens forms an image of the subject on the rotating disk. This disk is pierced with a series of small holes or apertures arranged in the form of a spiral; and, as the disk rotates, the apertures trace across the image one after the other in a series of parallel lines. The frame limits the size of the image and prevents more than one aperture being in the image at one time. Light, passing through an aperture as it travels across the image, falls in the light-sensitive cell and generates a picture current proportional to the brightness of the image from point to point along strips taken one after the other across the image.

In any system such as that outlined above, which depends upon scanning an image of the view as formed by a lens, the efficiency of the system is ultimately limited, for any given size of image that can be scanned, by the ratio of aperture to focal length of the best lens that can be secured. Experiments show that, with the best lens available to form a one-inch-square image, it would be necessary to illuminate a subject with a 16,000 candle power arc at a distance of about four feet in order to secure an image bright enough for a photoelectric cell to give an output current above the noise level in an amplifier system. In other words, television would apparently be extremely inconvenient to the subject if it were to be carried out from an image formed by a lens.

In the system actually used for television transmission, this apparent limitation has been evaded by reversing the entire optical system of Fig. 1 and arranging it as shown diagramatically in Fig. 2. Instead of scanning an image of the subject, the actual subject is scanned directly by a rapidly moving spot of light. An illustrative laboratory set-up, Fig. 3, shows the

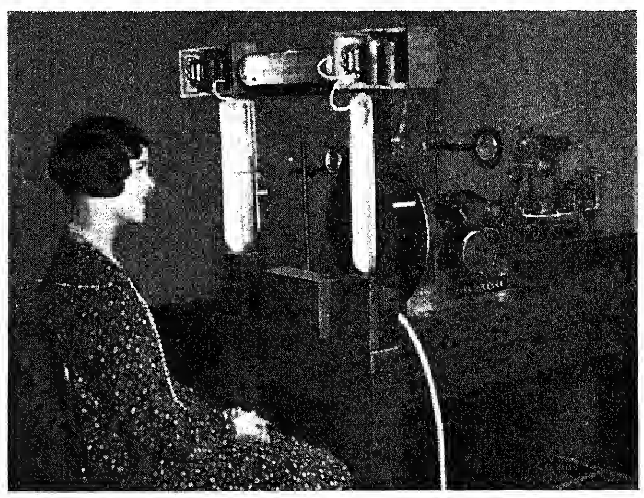

Fig. 3—Illustrative Transmitting Apparatus

Light from the arc lamp is condensed on the disk, which is driven by a high frequency synchronous motor. The disk carries a spiral of pin hole apertures, each of which in turn projects a moving spot of light on the subject. Reflected light is collected by three large photoelectric cells

arrangement of parts in such a transmitting station. A fifteen-inch disk rotating approximately eighteen times per second carries a series of fifty small apertures arranged in the form of a spiral. A beam of light is condensed by a lens from a 40-ampere Sperry arc to intensely illuminate a limited area in the path of the moving apertures; and a slender, intense beam of light passes through each aperture as it moves across the illuminated area. A frame in front of the disk permits

light to emerge from only one aperture at a time and the lens in front of the disk focuses an image of this moving aperture on the subject. As a result of this arrangement the subject is completely scanned in a series of successive, parallel lines by a rapidly moving spot of light, once for each revolution of the disk; and on account of the transient nature of the illumination the

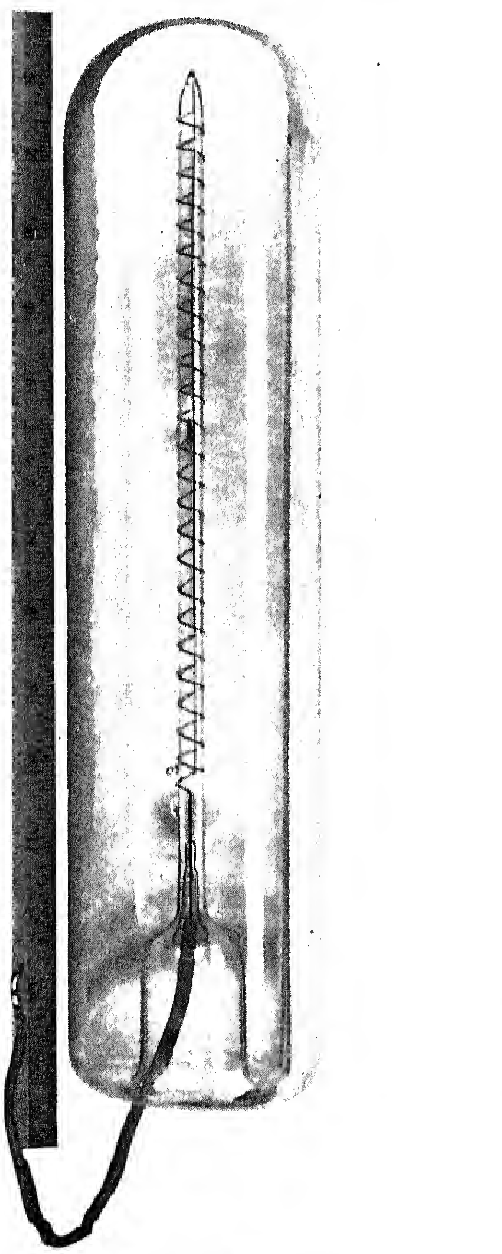

FIG. 4 LARGE PHOTOELECTRIC CELL

The cell presents forty square inches of photo-sensitive surface to receive light reflected from a subject

subject is scarcely aware that he is being exposed to it.

As the spot of light traces across the subject, light is diffusely reflected or scattered from the subject in all directions, and some of the light that is reflected forward passes into three large photoelectric cells placed just in front of the person who is being viewed. The current outputs from the three photoelectric cells operate in parallel into a common amplifier system. As the beam of light passes, for instance, across a person's eyebrow less light is reflected to the photoelectric cells, and as the beam passes across his forehead more light is reflected. Since the current output from the photoelectric cells is proportional to the received light, the current follows accurately the brightness of the various elemental areas of the subject's features as he is traced over by the scanning beam. This fluctuating current is unidirectional.

The actual operation of such an optical system, its influence on the lighting effects and quality of the reproduced image, may best be understood by noting that optically the system is identically the same as if all of the rays of light were reversed in direction to give an optical system equivalent to Fig. 1. The television apparatus sees the subject exactly as if rays of light came out of the photoelectric cells to illuminate the subject; the lens formed an image of the subject on the disk; and the apparatus scanned this image and reproduced it at the receiving end. The lights and shadows seen in the image are the same as if the subject were illuminated by three large lights in the positions of the photoelectric cells and looked at from the position of the lens. It also follows from the above considerations that, within its range of resolving power, this scanning method will not only reproduce a plane subject, such as a drawing, but that it will also faithfully reproduce three-dimensional figures with sharp edges and elevations and depressions, just as well as they could be reproduced in a photograph.

In addition, because the light passes in an approximately parallel beam through a disk aperture, the slender beams of light sweeping across the region in front of the transmitter just barely overlap each other even at a considerable distance from the apparatus. Consequently, it is not necessary that the subject be at the exact positions at which the small apertures are sharply focussed; and within wide limits no confusion results as the subject moves toward or away from the apparatus. The brightness as well as the size of the received image decreases as the subject moves away from the photoelectric cells; and for good transmission of the human features, which reflect very little blue light to which the photoelectric cells are sensitive, a person should not be more than a few feet away from the cells.

This method of scanning permits two very large gains to be made in the amount of light available for producing photoelectric currents. The transient nature of the light permits a very intense illumination to be used without inconvenience to the subject. Furthermore, the optical efficiency of the system is not limited by the apertures of available lenses; but can be increased by using large photoelectric cells and more than one cell connected in parallel.

The photoelectric cells of the potassium hydride, gas-filled type used in the transmitting stations, were specially constructed for the purpose and are probably

the largest photoelectric cells that have ever been made, Fig. 4. Three of these cells present an aperture of 120 square inches to collect the reflected light.

With this large collecting area and the strong light intensity that can be used for the transient illumination, the cells give an electrical output that, though still extremely small, is safely above the noise level of an amplifier system.

subject seated in front of it. The apparatus sees the person from light reflected back into the three large cells located just behind the screened openings in the case.

The variations of the feeble picture currents delivered from these photoelectric cells are highly amplified and transmitted over a wire or radio channel of communication by circuits described elsewhere in this series of articles. At the receiving station this current shape is re-amplified, impressed on a direct current, and finally produces an image in the receiving apparatus.

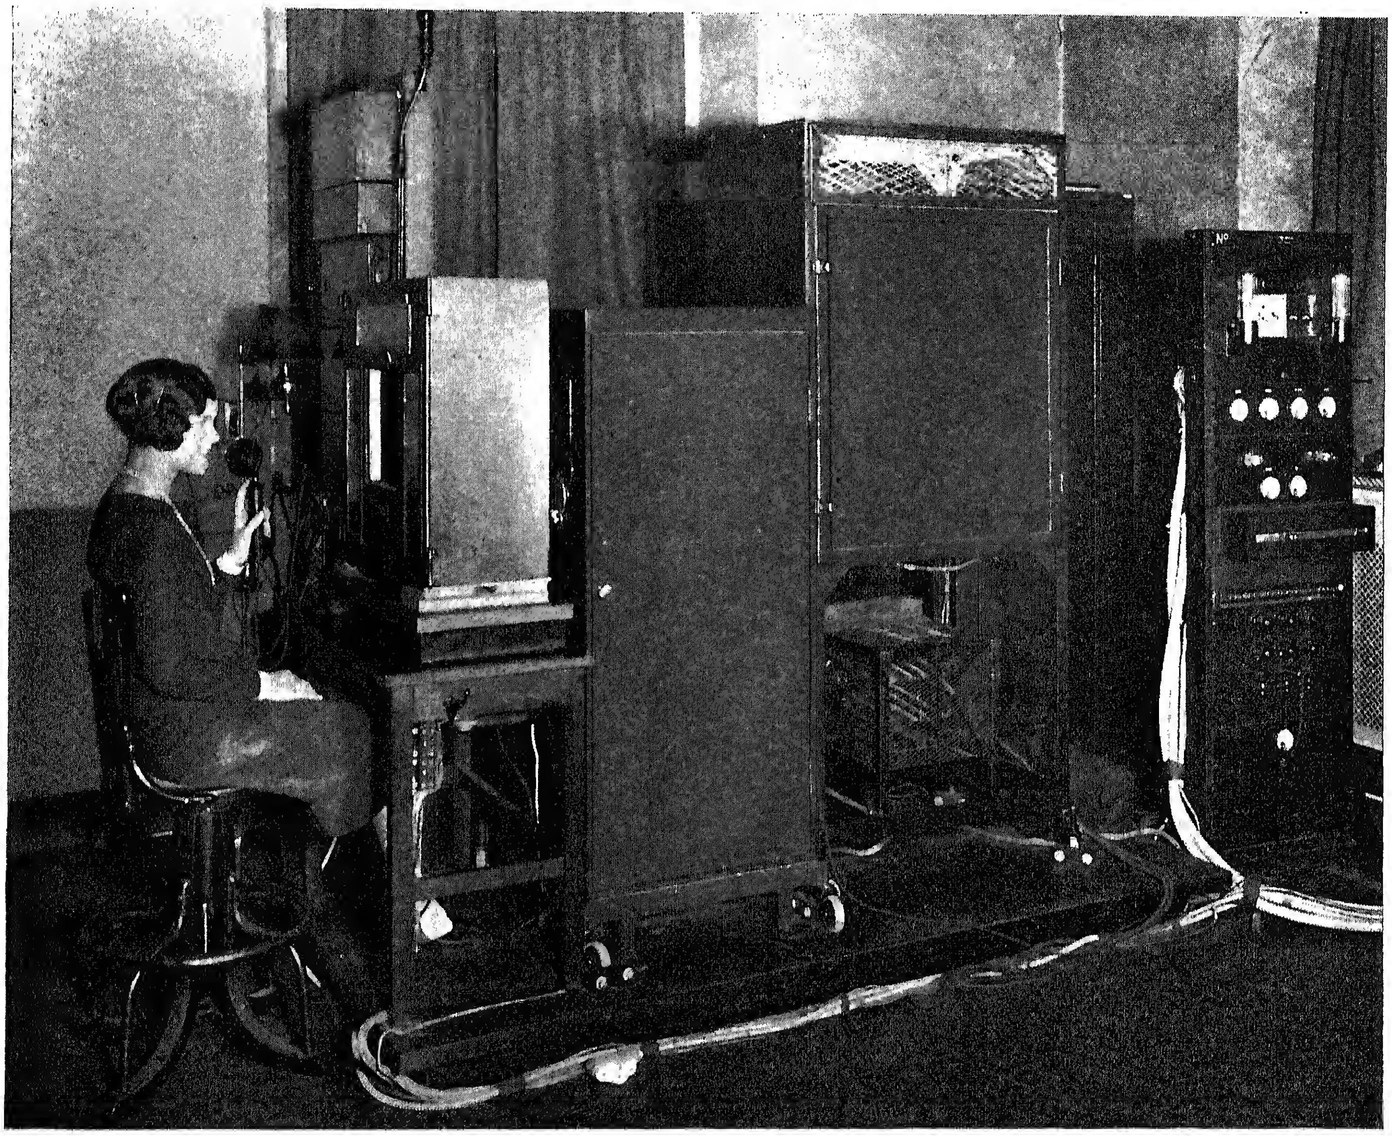

FIG. 5—TELEVISION TRANSMITTING APPARATUS

Sweeping beams of light pass out through the tunnel-like opening in the photoelectric cell case; light reflected from the subject is collected by three large photoelectric cells behind the screened openings

A photograph, Fig. 5, shows the details of a television transmitting station as it is operated in the field. The arc, rotating disk, and photoelectric cells are contained in separate cabinets and alined as shown in the photographs. The three photoelectric cells and first stages of amplification are mounted in a shielded, soundproof case. The slender, sweeping beam of light coming from the disk cabinet passes through the tunnel-like opening in the photoelectric cell case and scans the

A photograph, Fig. 6, shows an illustrative arrangement of the parts in one type of television receiver. An essential part of this type of receiver is a disk similar to the one at the transmitting station and also provided with fifty small apertures arranged in the form of a spiral. The driving motor rotates the disk in exact

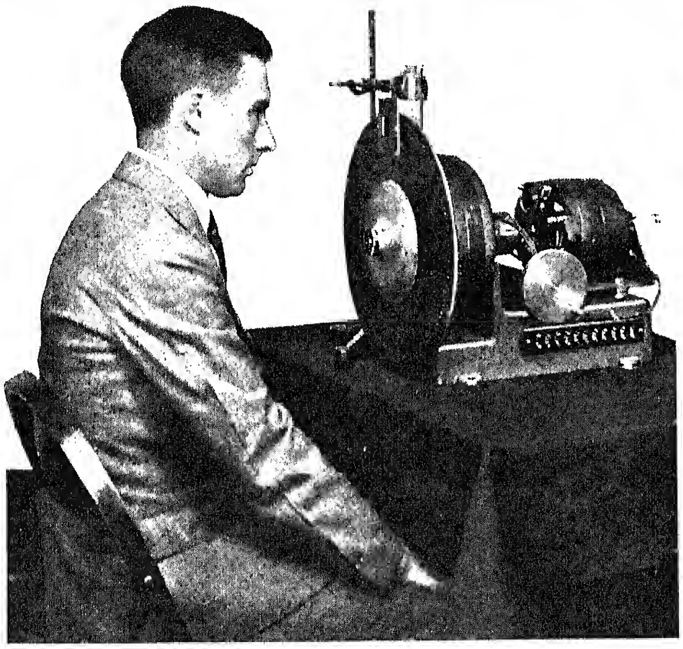

FIG. 6—ILLUSTRATIVE RECEIVING APPARATUS

A neon lamp operated from the picture current illuminates a series of small apertures as they pass across the field of view; the observer sees an image reproduced in the frame

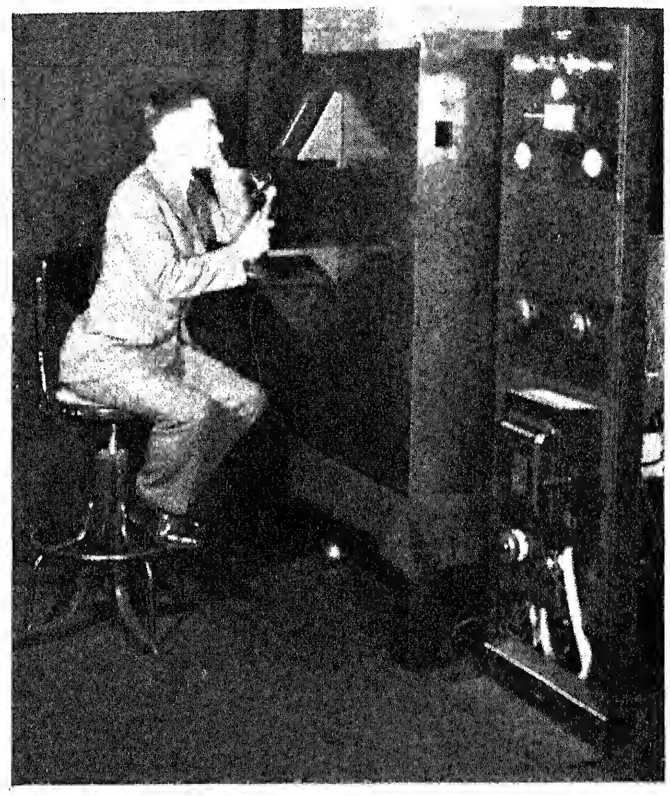

FIG. 8—DISK RECEIVING APPARATUS

The observer looks through the shielding window at a picture on the 36 inch disk.

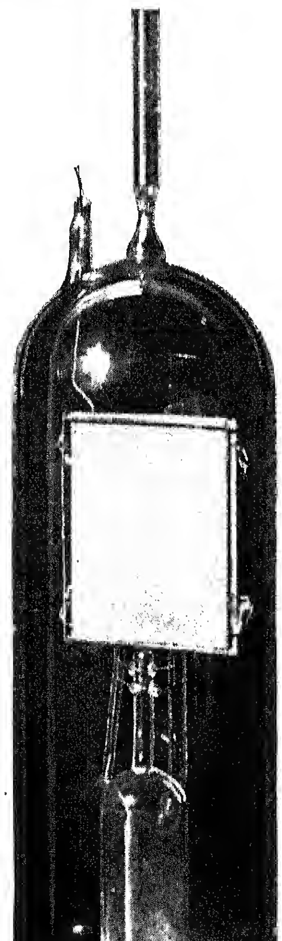

FIG. 7—NEON RECEIVING LAMP

The rectangular cathode is covered by a uniform layer of glow slightly larger than the field of view on a television disk

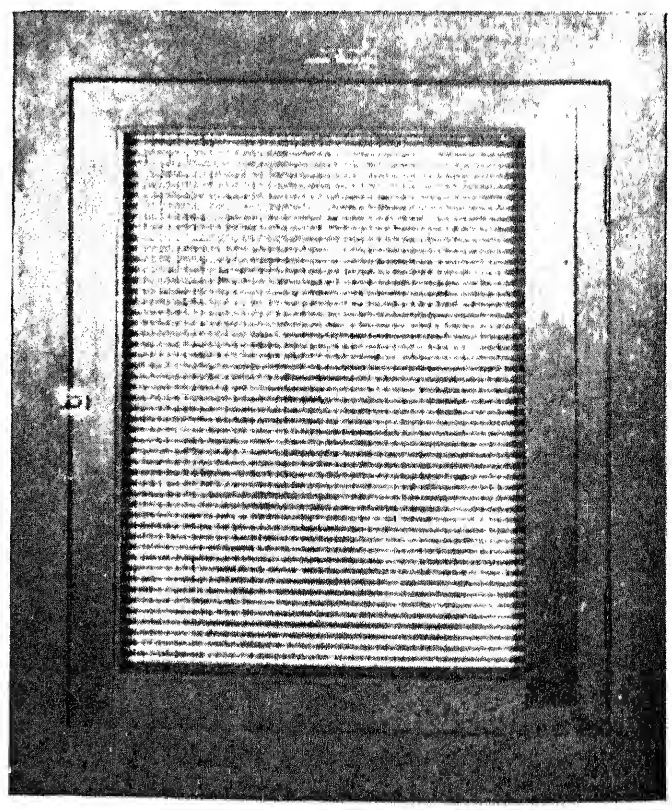

FIG. 9—LARGE GRID

The large grid is a neon lamp with 2500 electrodes on a tube bent back and forth to form a luminous screen that is visible throughout a large auditorium

synchronism with the one at the transmitting station. The observer looks at a small rectangular opening or frame in front of the disk. This frame is of such dimensions that only one aperture can appear in the field of view at a time. As the disk rotates, the apertures pass across the frame one after the other in a series of parallel lines, each displaced a little from the preceding one until in one revolution of the disk the entire field has been covered. Beyond the disk is a special form of neon glow lamp shown in detail by Fig. 7. In this lamp, the cathode is a flat metal plate of a shape and area sufficient to fill entirely the field defined by the frame in front of the disk. The anode of the glow lamp is a similar metal plate separated from the cathode by only a very small space (about one millimeter). At the proper gas pressure this space between the plates is within the "cathode dark space" where no discharge can pass. As a consequence, the glow discharge develops on the outer surface of the cathode, where it shows as a perfectly uniform, thin, brightly glowing layer.

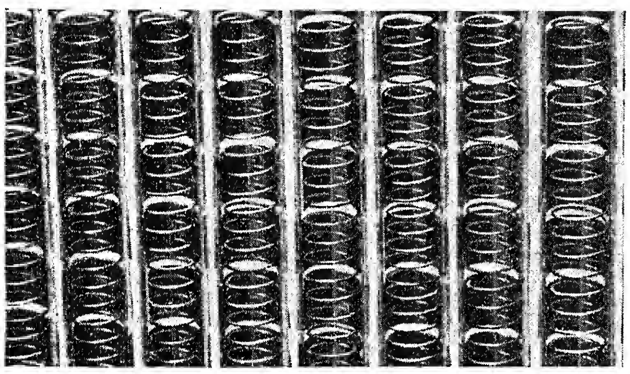

FIG. 10—DETAILED STRUCTURE OF THE GRID

The exterior electrodes are pieces of metal foil cemented to the outside of the tube. The interior electrode is a long spiral of wire

As an aperture in the disk moves across the field, the observer, looking through at the neon lamp behind the disk, sees the aperture as a bright point. When the disk is rotating at high speed, the observer, owing to the persistency of vision, sees a uniformly illuminated area in the frame, provided that a constant current is flowing through the lamp. (The line structure that would otherwise appear in the field is largely eliminated by using apertures that slightly overlap in their paths across the field.)

The brightness of the neon lamp is directly proportional to the current flowing through it; and when a picture is being received, the lamp is operated directly from the received picture current. As a result of the system just described, there is at any instant, in the field of view at the receiving station, a small aperture illuminated proportionally to the brightness of a corresponding spot on the distant subject. Consequently, the observer sees an image of the distant subject reproduced in the frame at the receiving station.

Fig. 8 shows the external appearance of the disk type of receiver in which the images appear. The disk rotates inside of a rectangular cabinet and the observer views the image through the shielding window. The largest disk, three feet in diameter, gives a 2 in.

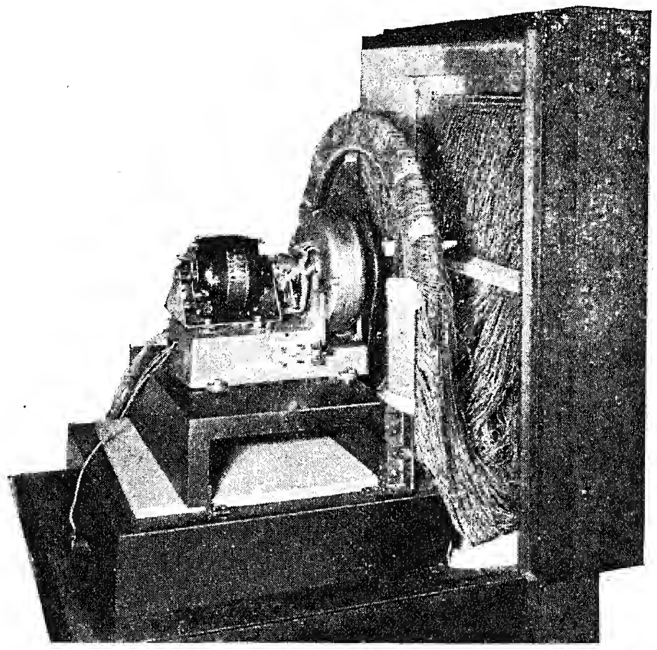

FIG. 11—DISTRIBUTOR AND WIRING

High frequency current is distributed by 2500 wires to successive electrodes of the grid from 2500 bars on a high speed distributor

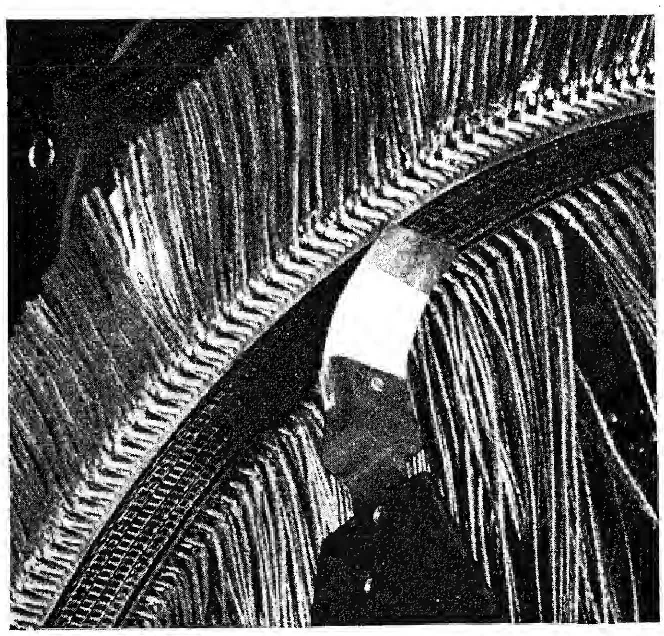

FIG. 12—DETAILS OF THE DISTRIBUTOR

The bars are arranged in four rows each displaced with respect to the other three. The sliding brush is a strip of thin sheet metal

by 2½ in. rectangular image. Each television receiver is also equipped with a telephone receiver and transmitter; and it is possible for the observer to both see and converse with a distant person at the same time.

Considering the limited number of picture elements, a surprising amount of detail can be transmitted with this television system. A distant person can be seen and easily recognized and his motions can be plainly followed as he talks into a transmitter, turns the pages of a magazine, and goes through other similar motions. Large sized pictures in a magazine can be seen as the subject turns the pages and looks at them himself.

An auxiliary television receiving system also accompanies each transmitting set and enables the operator to see that he is sending a satisfactory picture current out over the channel of communication. This auxiliary or pilot picture is formed on the scanning disk itself. A small fraction of the outgoing picture current is tapped off and amplified to operate a neon lamp, which is placed behind the disk ninety degrees around from the scanning beam. An image of the subject may thus be seen on the scanning disk just as at a receiving station. To correct for the ninety degree phase shift, the spiral of apertures on the transmitting disk is continued by additional apertures a quarter of a turn beyond the starting point. The first turn alone of the spiral is used for scanning; and the last turn alone, to form the pilot image; consequently, this image appears exactly in frame. A small mirror on the front of the motor cabinet reflects this image to the operator and enables him to see the character of the picture that he is sending out over the channel of communication.

When it is desirable to present television images to a large audience a special grid type of receiver is used. The grid has the appearance of an illuminated screen and can be seen throughout a large auditorium. The image is not projected on the screen from a lantern like a moving picture; such optical projection would be inefficient and demand the electrical control of an impractical amount of light. The picture current itself is distributed by a commutator to successive elemental areas of a large neon lamp. This lamp, as shown in Fig. 9, consists of a single, long, neon-filled tube bent back and forth to give a series of fifty parallel sections of tubing. The tube has one interior electrode and 2500 exterior electrodes cemented along the back side of the glass tubing, Fig. 10. A high frequency voltage applied to the interior electrode and any one of the exterior electrodes will cause the tube to glow in front of that particular electrode. The glow discharge actually passes to the inside wall of the glass tubing and the high frequency current flows by a capacity effect out through the glass wall to the exterior electrode. The high frequency voltage is commutated to the electrodes in succession from 2500 bars on a distributor, Fig. 11, with a brush, Fig. 12, rotating synchronously with the disk at a transmitting station. Consequently, a spot of light moves rapidly and repeatedly across the grid in a series of parallel lines one after the other and in synchronism with the scanning beam at the transmitting station. With a constant exciting voltage the grid appears as a uniformly illuminated screen; but, when the high frequency voltage is modulated by the received picture current, an image of the distant subject is produced on the screen and his motions can be followed just as in the smaller images formed on a disk.

This method of presenting television images to a large audience permits a very efficient use of the available energy to reproduce a picture. The modulated current produces a glow discharge that exactly covers an elemental area of the picture on the screen and is viewed directly by the audience; consequently, there is absolutely no loss of energy after the picture current has been converted into light. In addition, each illuminated area of the screen responds to the picture current in the same manner; the exterior electrodes are exactly alike, and the use of a single tube assures the same pressure and purity of neon throughout the grid.

Fig. 9 shows such a screen set up for demonstration in an auditorium. A loud speaker is mounted just below the screen and it is thus possible for a large audience to both see and listen to a distant person at the same time.

SECTION II

The Television Signal Wave

So far it has been assumed that the electrical signal wave is perfectly transmitted between the conversion devices which transform the light variations into electrical variations and back again. Perfect transmission is, however, impossible with practical apparatus. There are certain requirements placed upon the generated signal wave by the characteristics of practical communication channels, and reciprocally certain demands are made upon a transmission system by the inherent nature of an adequate television signal. In addition to exploring these mutual requirements experimentally it is desirable to analyze them in such a way that, as far as possible, quantitative expression may be given to them. This expression in the case of the signal wave is best made by the methods of the Fourier analysis; considering the signal as made up of many sine wave components of various frequencies. The requirement on the signal may then be described in terms of these components and the requirements on the connecting transmission system in terms of attenuation and phase characteristics over a band of frequencies. These requirements will now be discussed as a basis for the subject matter of the succeeding section of this paper and of the following companion papers of this group on *Wire Transmission Systems for Television* and *Radio Transmission Systems for Television*.

The problems to be discussed may be conveniently considered under three headings:

(a) The Character of the Television Signal.

(b) Requirements upon the Signal Wave Set by the Characteristics of Available Transmission Channels.

(c) Requirements which the Transmission Channels must meet in order to carry Television Signals.

(a) *The Character of the Television Signal.* As we have seen, the voltage produced across the resistance in series with the photoelectric cell is a fluctuating unidirectional potential. The generated signal therefore has frequency components beginning at and including zero frequency. The value of the voltage at any instant is roughly proportional to the average reflected illumination at that instant from an illuminated spot whose size depends upon the apertures in the scanning disk. At any point where there is a sudden change in the tone value of the subject there will also be a sharp change in the generated voltage. It will, therefore, be seen that but for the limits of speed of action of the photoelectric cell and its connected circuits the generated signals would tend to include components over the whole frequency range up to infinity. Since it is possible to effectively transmit but a limited range of these components, the width and location of the frequency band necessary for the acceptable reproduction of a given size and structure of image must be determined. It is convenient to consider first the low frequency end of the band.

In the early experimental work it was soon found that in attempting to amplify the lower frequencies by the use of direct current amplifiers, unstable conditions of operation were reached before sufficient amplification was obtained to operate the receiving apparatus. Experiments were then made with resistance-condenser coupled amplifiers which showed that, if the efficiency of such an amplifier at the frequency equal to the number of pictures sent per second, was not more than about two T U below its average efficiency for the transmitted range, acceptable reproduction of the picture was secured together with stable operation of the amplifiers. When the low frequency cut-off of the amplifier was set much above this, spurious shadows were introduced into the picture. That there will be a critical lower frequency for the transmission of an unchanging scene is obvious since the Fourier series into which the signal may be analyzed starts with a constant term and the sine wave terms begin with the picture frequency and include a vast number of its harmonics. If the constant component (d-c.) is removed, the lowest frequency which remains to be transmitted is therefore the picture frequency.

The effect of removing the d-c. component of the signal can be qualitatively traced in a simple manner. Imagine three types of still pictures or scenes to be transmitted by the system. Let the first be quite dark in general effect and require fluctuations in the signal current of a certain average amount for its transmission. Such a picture would have a low direct current component. Let the second picture consist largely of medium grays and require about the same fluctuations in signal intensity for its delineation. Such a picture will have a medium direct current component. Let the third picture be very light in general effect with such difference in light and shadow as would require the same fluctuations in signal intensity as the other two pictures. Such a picture would have a relatively high direct current component. In passing through a resistance-condenser coupled amplifier, the signals for all three types of pictures would be changed from fluctuations superimposed upon direct current to alternating currents, all of about the same average value.

At the receiving end of the circuit the direct current component may be reinserted by superimposing the alternating current fluctuations upon a fixed value of direct current such as the steady state current in the last amplifier tube. This direct current component would give the best average results if it corresponded to that suitable for the gray picture, which would, of course, then be most nearly correctly reproduced. However, most of the detail of the dark and light scenes would also be reproduced though the tone values would be distributed about a medium gray. Fortunately a change in character of this kind has proved for the most part unimportant. Where it is important it can be taken care of very simply by providing, at the receiving end, means, either manual or automatic, for changing, in accordance with the type of scene being transmitted, the magnitude of the unidirectional current upon which the received alternating current is superposed, which amounts simply to the restoration of the direct current.

In the case of scenes which are changing, however, frequencies lower than picture frequency will in general be generated and their suppression may be expected to affect to some degree the perfection of the picture. In effect, these frequencies are analogous to changes in tone values in the case of still pictures and their elimination results in fluctuations in the apparent brightness of the image. This effect is not disturbing with many types of subjects, as for example in the reproduction of the face.

One remarkable result of not transmitting the direct current component of the signal in the case of the reflected beam method of scanning is that the television transmitting apparatus can be located and operated in a well-lighted room, for if this general illumination is constant it simply increases the direct current component of the signal. Similarly if the scene itself contains a source of steady light, this will be visible only in so far as it reflects the scanning beam.

Turning now to the upper part of the frequency range, experimental data on the highest necessary

components were obtained by the use of circuits with low pass instead of high pass characteristics. With the television terminal apparatus operating at 17.7 pictures per second, it was found that a filter whose phase distortion had been corrected over practically all of its pass band of 15,000 cycles produced a degradation in image quality which was just detectable when the human countenance was being transmitted. Since the electrical terminal apparatus without the filters

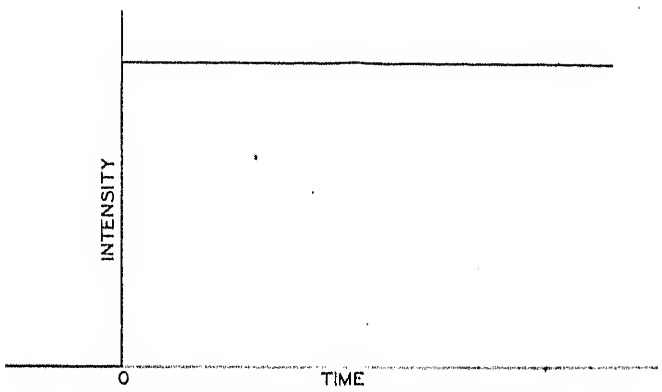

Fig. 13 Elementary Signal Change

would efficiently transmit frequencies higher than this, the experiment showed either that frequencies higher than this were not present in the generated signal, that they were not effectively reproduced, or that they contribute little to the appearance of the image. This upper limit to the useful frequency range for this apparatus is rather lower than was anticipated from the initial survey but because of psychological factors (decreased discrimination of tone

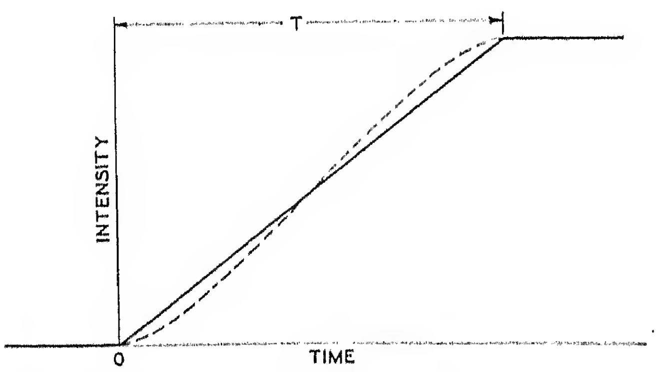

Fig. 14 Elementary Signal Change as Distorted by a Square Aperture

values for fine details, apparent improved resolution when the subject is moving, etc.) it proves satisfactory for television purposes.

It is of importance, however, to know where the limitation in frequency range occurs in the apparatus and how it might be modified. Considerable information on this point is obtained by studying the nature of the distortion introduced by the aperture in the optical system and that introduced by frequency limitation in the electrical part of the system. It is convenient to consider them together as the type of distortion turns out to be similar for the two cases. This distortion may be considered most simply in relation to the type of signal corresponding to a sudden unit change in tone value at some point in the subject. With an ideal television system in which the instantaneous values of signal current are at all times proportional to the tone values of the points being scanned, the resulting signal would be represented by the graph of Fig. 13. Such a consideration involves no real loss in generality as any signal shape may be considered as the result of infinitesimal abrupt changes in intensity.

It is readily seen that if a square aperture passes with uniform velocity over a part of the picture having an abrupt change from dark to light the result is that we get a signal from the photoelectric cell which, instead of building up instantaneously, builds up linearly during a time, T, Fig. 14, which is the time required for

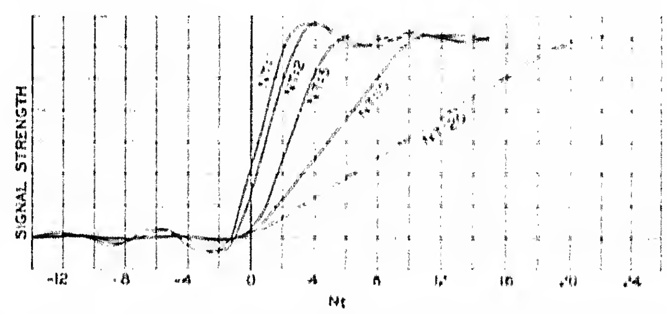

Fig. 15 Elementary Signal Change as Distorted by a Square Aperture and by Ideal Frequency Restriction

the aperture to pass a given point.[1] The net effect is an apparent sluggishness in the response of the system. The dotted curve of Fig. 14 shows the integrated illumination passing through a circular aperture of a diameter corresponding to the same time, T, for the condition of Fig. 13. Due to the simpler analysis the discussion will be carried out in terms of the square aperture though the sluggishness due to the round one is seen to be slightly less.

Now this kind of sluggishness in response is quite similar to that introduced in the electrical part of the system when the upper frequencies are cut out or not transmitted as efficiently as the lower ones. The effect of frequency limitation can be investigated theoretically in a fairly simple fashion if we make the ideal assumption that all frequencies are transmitted without distortion up to a cut-off frequency, f_c, and extinguished beyond it. In Appendix 1, it is shown how the signal of Fig. 14 is affected by a frequency limitation of this type. We can then plot a set of curves as shown on Fig. 15 from which we can

1. This effect of aperture distortion was pointed out in the paper "Transmission of Pictures over Telephone Lines" by Ives, Horton, Parker, and Clark, *B. S. T. J.*, April, 1925.

measure the total time of rise due to both the aperture and frequency limitation. The abscissa is the product of $N = 2\pi f_c$ and the time, t. Any one curve serves for a wide range of values of N and T as long as their product is the same. Call the new time of rise τ. Then we can plot a relation as on Fig. 16 between $N\tau$ and $N T$ from which we can draw conclusions as to the relative effects of aperture and frequency distortion.

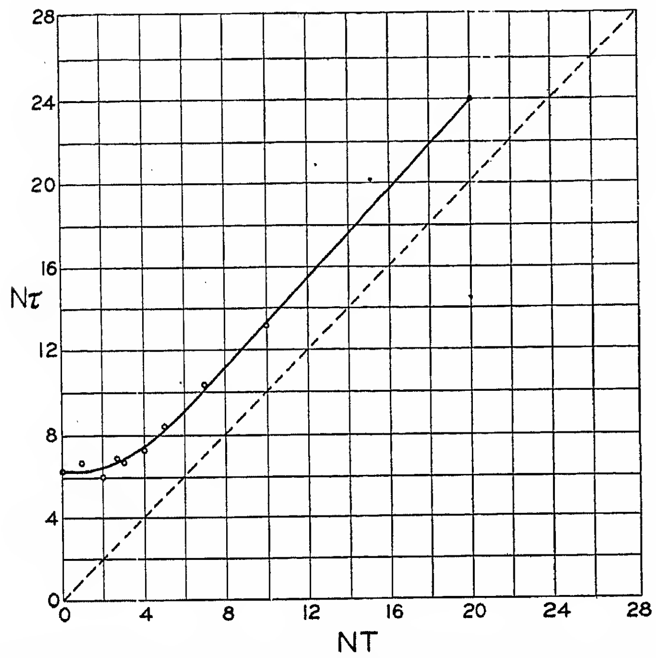

Fig. 16—Sluggishness Due to Distortion as a Function of the Aperture Width and Frequency Restriction

Below the knee of this curve we have approximately $N\tau = 2\pi$

$$\tau = \frac{1}{f_c}$$ and the frequency cut-off determines the whole distortion.

Similarly above the knee

$$N\tau = N T + \pi$$

$$\tau = T + \frac{1}{2 f_c}$$ and the controlling influence is that of the aperture.

Unless one effect is much more easily remedied than the other, the knee of the curve appears a reasonable point to select for operation. At the knee $N T_k = 2\pi f_c T_k = \pi$ and $T_k = 1/2 f_c$. At this point the total lag is not much greater than that due to the frequency restriction alone and is $\frac{1}{f_c}$ or twice T_k. That is, at this point, the additional lag in the time of rise of signal due to the restricted frequency range is equal to that due originally to the aperture, though the additional lag due to the aperture is not much greater than that due to the frequency restriction alone. For a square aperture in a square picture of 2500 elements sent 16 times a second $T = \frac{1}{40{,}000}$ of a second, and $f_c = 20{,}000$ cycles at the knee of the curve. The point on the curve where the effect of frequency restriction introduces a sluggishness in following light changes comparable to that introduced by a square aperture is the same frequency as that arrived at as the upper limit to useful frequencies by considerations from still picture transmission, in the introductory paper by Mr. Ives. Its value is equal to one-half the number of picture elements.

It has furthermore been found possible to determine ideal electrical transmission characteristics or equivalent transfer admittances of circuits which produce exactly the same distortions as various types of apertures. While it appears impossible at present to construct a physical circuit which will produce such characteristics over the whole frequency range, the problem is not difficult if we limit ourselves to the most important frequency band. This is of interest as it points out the possibility of compensating for the effect of the aperture by putting in an electrical network with frequency transmission characteristics the inverse of those so determined. Within the range of important frequencies it turns out that the effect of the aperture is the same as that of a network which changes merely the relative amplitudes of the frequencies into which the picture signal may be analyzed. Neglecting constant multiplying factors, the relative variation

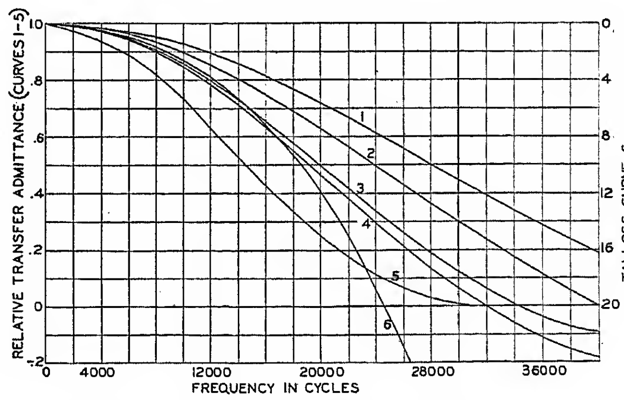

Fig. 17—Equivalent Transfer Admittance of Various Apertures

over the frequency range for a square aperture is given by the factor $\frac{\sin T\,\omega/2}{\omega}$ and for a round aperture by $\frac{J_1\,(T\,\omega/2)}{\omega}$ where, as before, T is the maximum time for the aperture to pass a given point and J_1 is the Bessel's function of the first order. The derivation of these factors is given in Appendix II. On Fig. 17, Curve 1

gives the relative values of the equivalent transfer admittance for the square aperture and Curve 2 for an inscribed circular aperture, both in case of a 50 line scanned picture which is square and sent 16 times per second. T then is equal to $\frac{1}{40{,}000}$ sec.

In the system as set up for demonstration the image is rectangular with the vertical and horizontal dimensions in about the ratio 5 to 4. The circular aperture

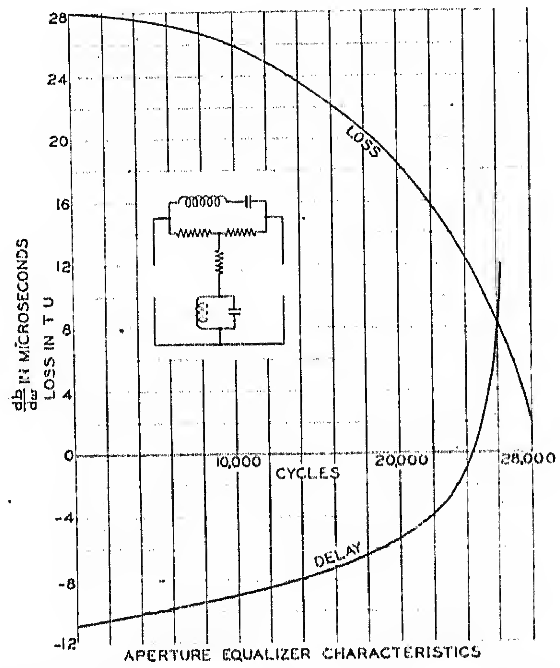

FIG. 18—CIRCUIT FOR EQUALIZING THE APERTURE EFFECT AND ITS AMPLITUDE AND PHASE CHARACTERISTICS

is about $1\frac{1}{4}$ times 1/50 of the vertical height and the scanning is done 17.7 times a second. T is then 3.53×10^{-5} seconds and Curve 3 gives the corresponding frequency characteristics. Curve 4 shows that a square aperture of the same area as the circular aperture for Curve 3 gives a fairly good approximation to Curve 3. Curve 5 gives the combined effect of the two circular apertures, sending and receiving, corresponding to Curve 3. Curve 6 is Curve 5 plotted in terms of T U on the right hand scale.

An inspection of this last curve indicates that this frequency attenuation characteristic of the aperture introduces a considerable loss at 15,000 cycles and leaves little of the signal components above 20,000 cycles. To see if an electrical circuit of characteristics inverse to those of the aperture would materially improve the resolution of the image, the circuit[2], which, together with its frequency characteristics, is shown in Fig. 18, was inserted between the sending and receiving amplifiers. It was designed to compensate for most of the aperture distortion and its phase distortion was made small below 20,000 cycles. On the fan-shaped test pattern of Fig. 19 a noticeable improvement was observed, the black and white angles being resolved closer to the tip of the pattern. In the case of faces the improvement appeared to be very little but could be detected in the slightly better definition of sharp narrow lines such as the frames of horn rimmed spectacles. When a system of considerable attenuation is employed between the sending and receiving terminals it would in general be preferable to split the equalizing between the sending and receiving ends to make the best use of the sending end power in riding over interference.

In arriving at the amount of electrical equalization which shall be adopted in any particular case it must of course be borne in mind that as the aperture is made narrower the amount of distortion introduced by it becomes less. As we narrow the aperture, however, the available illumination becomes less and the signal generated by the photoelectric cell becomes smaller. A limit is therefore soon reached at which the difficulties of amplification become greater than the difficulties of equalization and a minimum practical aperture width is thereby determined. If the distortion is corrected by narrowing the aperture it is apparent that the apparatus will generate, at but little lower than the

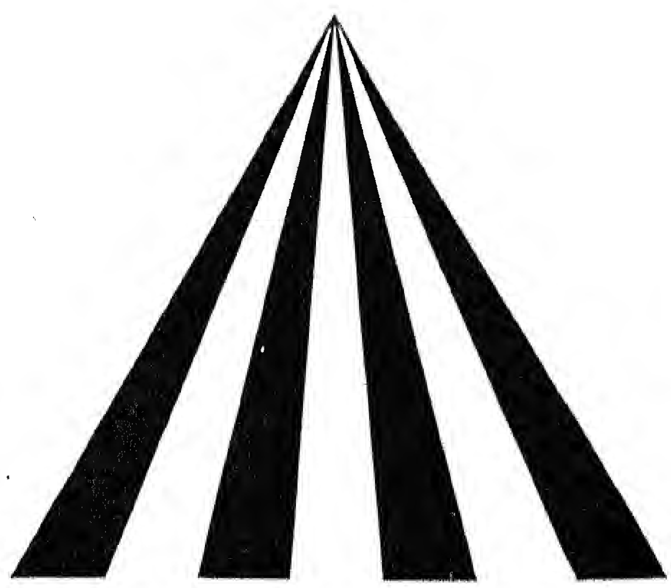

FIG. 19

correct relative efficiency, frequencies much higher than those thought necessary from the more general considerations in Mr. Ives' introductory paper. Decision as to the desirable frequency transmission band for the connecting communication channel would be no different for either method of reducing the distortion due to the aperture.

In summary then, we may say that experiment and theory show that the lowest frequency essential to

2. This is a constant resistance type of corrective network or equalizer. See Chap. XVIII, "Transmission Circuits for Telephonic Communication," K. S. Johnson.

satisfactory results is the picture frequency, and the highest frequency required is approximately one-half the number of picture elements scanned per second.

(b) *Requirements Upon the Signal Wave Set by the Characteristics of Available Transmission Channels:* The limitations upon the signal wave set by present available communication channels are:

1. The magnitude of the signal necessary to override the interference to which such channels are subject.

2. The frequency range. which such channels can transmit.

The first of these is self-explanatory. It determines the required amplification and load capacity of the transmitting apparatus. In the companion paper on *Wire Transmission Systems for Television* are the data on interference and on permissible signal to noise ratio which were used in the design of the terminal transmitting amplifiers to be described in the latter part of this paper.

In considering the frequency range of lines, it was apparent in the beginning that the wire channel might include sections of cable. With exsisting loading systems for such cables a frequency range of not over 40,000 cycles appeared available. The terminal apparatus was therefore designed to deliver a generated signal whose essential components lay well within this limit, and the laboratory tests mentioned in the preceding section showed that this requirement was met.

A lower frequency limit was imposed by the necessity of a transformer for joining the transmission line to the terminal equipment. Fortunately it proved possible to design transformers as described in the final part of this paper in which this limit was at or below the essential low frequency limit found in the preceding discussion of the signal wave.

(c) *Requirements Which Transmission Channels Must Meet in Order to Carry Television Signals.* We have shown that a certain band width of frequency components is essential to the adequate reproduction of the image. This sets the frequency limits of the transmission channel which must be provided. It is essential, however, that within these transmission limits the channel should present a reasonably uniform attenuation, and that the phase relations should be fairly accurately maintained. The problem as presented to the transmission engineers of wire, radio, and terminal equipment for the recent demonstration was to meet the following requirements:

First, transmission must be provided for frequencies between about 10 cycles and 20,000 cycles.

Second, the amplitude frequency characteristics within this range should be uniform to about $\pm$ 2 T U.

Third, the phase shift through the range should be maintained so that the slope of its characteristic as a function of frequency is constant to $\pm$ 10 or 20 microseconds over all but the lowest part of the frequency range. There, about 50 times this limit was considered the maximum permissible.

These requirements were arrived at by considerations based on theory and experiments on television and analogy to similar requirements in telephotography. The first requirement follows directly from the discussion of the essential frequencies in the signal. The following paragraphs are intended to illustrate the significance of the remaining requirements.

As we have as yet no quantitative measure of the goodness of reproduction of the image, the matter of the second and third transmission requirements on received amplitude and phase characteristics over the frequency scale is one which had to be decided largely on the basis of the experimental results and judgment based on general considerations. We have already seen that the removal of the very lowest frequencies simply changes the tone value of the whole picture. It may be similarly reasoned that departures from the average efficiency of transmission in the lower part of the frequency range would result in the appearance of diffuse shadows or high lights. Likewise, it may be concluded that broad deviations from the average efficiency of transmission in the uppermost part of the signal frequency range would result in the accentuation or the fading out of the finer detail of the scene. Steep slopes in the amplitude-frequency curve would result in the superposition of oscillations upon signals representing sudden changes in intensity. To reduce these effects every reasonable effort was made to keep the variations in the amplitude characteristic with frequency as slight as possible, aiming to hold these characteristics for the separate parts of the demonstration system to within $\pm$ 2 T U or better.

In addition to transmitting the component frequencies with the same relative efficiency as regards amplitude, it is also particularly essential in television to send them through the system with small relative phase shifts; that is, with constant velocity or what is equivalent, a phase shift proportional to frequency. It has long been known in optical theory that the envelope of a group of waves of nearly the same wave length and nearly the same frequency may travel along with a "group velocity" somewhat different from the phase velocities of the component elements. If the system has but small departures from a flat amplitude-frequency characteristic and from a linear phase shift frequency characteristic, it can be shown that the time of group transmission or "envelope delay" is given by $d\,b/d\,\omega$,[2] the slope of the curve obtained by plotting the phase shift, b, for the system, against the angular velocity, $\omega = 2\,\pi\,f$. The time of transmission of a crest for any sine wave component of frequency $\frac{\omega}{2\,\pi}$ is, of course, given by $\frac{b}{\omega}$. If $b = c\,\omega$, $\frac{b}{\omega} = c$

and $\frac{d\,b}{d\,\omega} = c$. Then the phase and envelope times of transmission are equal and all frequencies as well as their group envelopes get over in the same time. If b is given in radians, $\frac{d\,b}{d\,\omega}$ is given in seconds. In general a knowledge of b as a function of ω is necessary and sufficient to determine the phase distortion. A knowledge of $\frac{d\,b}{d\,\omega}$ as a function of ω is not sufficient to determine all factors in signal distortion. It is, however, often easier to measure with the needed accuracy and in transmission systems such as have been used for still pictures and television has proven a useful index of phase characteristics.

After a preliminary estimate from experience with still pictures that the limit on $\frac{d\,b}{d\,\omega}$ should be $\pm$ 10 microseconds, an electrical network consisting of five sections of a simple lattice structure was used for testing the effect of phase distortion with television apparatus. This network introduced negligible amplitude distortion and a drift in the value of $\frac{d\,b}{d\,\omega}$ of 50 microseconds over the frequency range of 0 to 20,000 cycles. Its effect was perceptible in blurring the image of a face and it decidedly affected a sharp pattern of two parallel lines of such width and spacing as to be just within the resolving power of the apparatus. This variation of $\frac{d\,b}{d\,\omega}$ was about 2½ times greater than that postulated. Hence $\pm$ 10 microseconds was agreed on as a desirable limit for $\frac{d\,b}{d\,\omega}$, though it was felt that this limit might be exceeded by a factor of two in restricted parts of the frequency band.

When this network was combined with a filter the slope of whose envelope delay curve was in the opposite direction so that over the greater part of the frequency range the combined delay of the two circuits was constant and equal to 140 microseconds, this time delay effect was very graphically brought out. Every time the combined circuit was cut in, the undistorted received image jumped to a new position a little over 10 per cent of the width of the picture to one side in the direction of scanning.

To see why $\frac{d\,b}{d\,\omega}$ should be maintained at a constant value, consider two sharply defined details near together in the picture which would produce a variation in signal intensity with time as indicated in Fig. 20. Imagine each to be cyclically continued so that the small detail defines a frequency f_1 and the other defines a frequency f_2. It is then known from Fourier analysis that the frequency spectra of the two details are chiefly concentrated around the frequencies f_1 and f_2. If $\frac{d\,b}{d\,\omega}$ is appreciably different at the frequencies f_1 and f_2 for any part of the system, the two details will be displaced relatively to each other along the line of scanning and, in most cases, if this shift is appreciable, some change in the shape of the signal wave defining each detail results with further increase in the distortion. The same relative shift would occur if the narrow detail were located upon the broader one in which case, such a shift would be more apparent. It would seem reasonable to expect then that differences in the envelope time of transmission comparable to a whole picture element (about 28 microseconds in the demonstration apparatus) would be noticeable.

In most images very few details will have signal

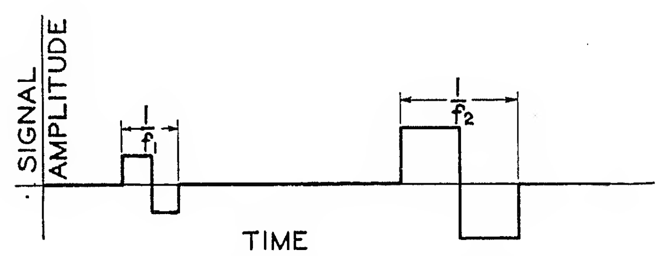

Fig. 20—Signal Details of Concentrated Frequency Spectrum for Illustrating the Effect of Envelope Delay

shapes, as in this special case, in which the frequency components are concentrated in narrow frequency bands. An abrupt change in signal strength, for instance, is represented by components distributed over the whole frequency range. We can imagine these frequencies divided into any arbitrary number of groups, each of which determines a wave form. When these wave forms are added together they will reproduce the original abrupt change in signal strength. If, however, they are sent through a system in which the envelope delays for the different groups are unequal, the individual wave forms will be relatively displaced and will no longer combine correctly. As a result the image is blurred. For some types of phase distortion the effect appears as an oscillatory transient following sudden changes in intensity.

It was furthermore found by experiment that the limit of $\pm$ 10 microseconds was not necessary for the lower frequencies. Reference to the delay characteristics of the transformers described in the latter part of this paper shows that in the lower part of the frequency

scale deviations from the nearly uniform value of delay at the upper frequencies appear of magnitude greater than 100 microseconds. When the signal was sent through these transformers, however, there was no observable distortion of the image. The requirements are therefore much more lenient at the low frequencies.

In the terminal apparatus the problem of meeting the above outlined phase transmission requirements was not a very serious one. The circuits involved are such that when a flat amplitude-frequency characteristic had been secured the phase distortion was also negligible.

SECTION III

Terminal Circuits for Sending and Receiving Television Signals

The preceding sections have discussed the methods by which an object, the image of which is to be transmitted, is made to control the time variations in a light, thus giving a luminous signal wave, and the means by which the image may be reconstructed with the aid of an electric signal wave corresponding to this initial luminous wave in its relative instantaneous amplitudes. Certain important relations between the characteristics of the signal wave and the resulting image have been pointed out. There remains the question of obtaining an electric signal wave suitable for long distance transmission and of providing for the control of the illumination at the receiving terminal by the electric signal wave as delivered by the transmission medium.

In the use of wire lines for television it is fortunately true that a suitably prepared open-wire circuit possesses a frequency range sufficient for the transmission of all the essential components of the signal wave. Details regarding the characteristics of the wire circuits are given in a companion paper by Messrs. Gannett and Green, from whose work are obtained data essential to the design of the terminal equipment. These data fix the power level at which the signal should be delivered to the line and the power level which will be available at the receiving end. When the transmission is by radio it is, of course, necessary to affect a frequency translation in order to secure a wave suitable for radiation and transmission through the ether. In this case, however, the radio system, which is described in a paper by Mr. E. L. Nelson, when considered as a whole may be conveniently taken as a system capable of the transmission of a signal wave occupying the same frequency range as that supplied to the wire circuits. In fact the design of the radio system is such that it may be used interchangeably with the wire line in so far as the remaining electrical terminal equipment is concerned.

The terminal circuits, then, fall into two groups: first, those used at the transmitting terminal for building up the wave controlled by the time variations in light to the power level required by the line and second, those used at the receiving terminal to bring the wave delivered by the line to the proper form for controlling the luminous sources from which the received picture is built up.

Transmitting Circuits

Starting with the photoelectric cell in which the initial luminous signal wave is converted to an electric signal wave, we are interested in the magnitude of various pertinent constants. The cell may be considered for our purposes as an impedance, the value of which is determined by the quantity of light reaching it. With no illumination at all this impedance is almost entirely a capacitance of the order of 10 m. m. f. When the cell is illuminated this capacitance becomes effectively shunted by a very small conductance which is roughly proportional to the square of the voltage between the electrodes. For a fixed potential the magnitude of this conductance is nearly a linear function of the illumination. With a suitable potential in series with the cell, then, there is obtained a current the amplitude of which is proportional to the quantity of light reaching the cell.

In order to connect the photoelectric cell to the amplifier there is introduced in series with the cell and its polarizing battery a pure resistance the voltage drop across which is used to control the grid potential of the first tube. It is desirable, of course, to make this resistance high in order to have available as much voltage as possible. Its value is, however, limited by two considerations. The added series conductance must not be so low that it appreciably disturbs the linear relation between the illumination and the total conductance of the circuit. The voltage drop must also be so small, in comparison with the total potential in the circuit, that the photoelectric cell operates at an approximately constant polarizing potential.

In view of the extremely small voltage of the electric signal wave as delivered by the photoelectric cell circuit, it is essential that great care be taken to prevent such interference as may enter the initial amplifier stages from approaching a comparable magnitude. The most troublesome sources of interference are electrostatic induction, electromagnetic induction, mechanical vibration, and acoustic vibration. By mechanical vibration is meant disturbances transmitted through the supports as the result of building vibrations and similar phenomena. By acoustic vibrations are meant impulses transmitted through the air which strike the several elements of the amplifier and cause motion which results in variations in their electrical constants. Electrical disturbances are reduced to a minimum by placing the amplifier as close as possible to the photoelectric cells, thereby keeping the leads short, which

avoids electrostatic pick-up and also prevents the formation of closed loops of any appreciable size, thus avoiding electromagnetic induction. The amplifier is provided with a very complete electrical shield and both the shielded amplifier and the photoelectric cells are placed in a carefully shielded cabinet.

The tubes used, namely the so-called "peanut" tubes, are under ordinary conditions, remarkably free from any microphonic action. At the very low signal levels used, however, certain extra precautions have to be taken against this effect. In addition to lining the amplifier box with sound absorbing material the tubes themselves have been wrapped in felt and placed within a heavy lead case. This prevents such acoustic disturbances as reach the interior of the amplifier container from having any noticeable effect on the tube. The lead container is supported entirely by an elastic suspension and thus serves a dual function, as the heavy mass, supported in this way, is capable of little response

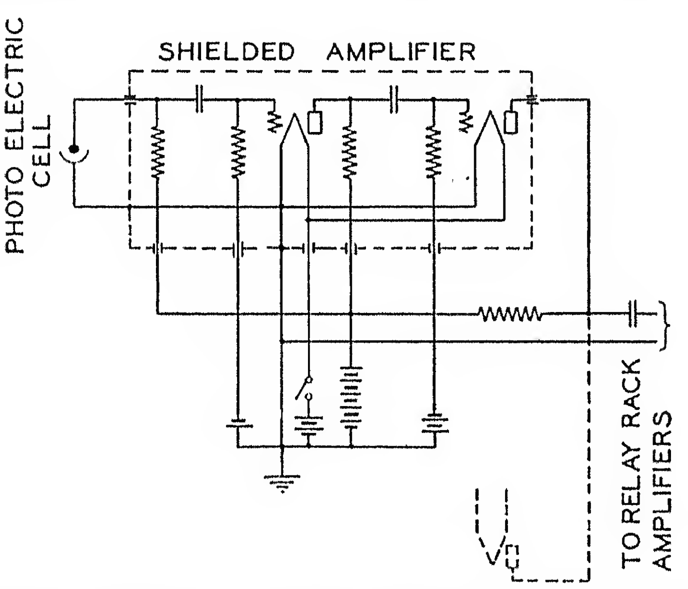

Fig. 21 Schematic of Vacuum Tube Amplifier Used with Photoelectric Cells

to such mechanical vibrations as may be transmitted through the cabinet and the walls of the amplifier shield. With these precautions it has been found possible to make the effect of all external disturbances of about the magnitude of the thermal disturbances referred to in the first part of the paper.

A schematic diagram of the amplifier tubes directly associated with the photoelectric cell is given in Fig. 21. Attention has already been called to the fact that the initial signal, that is, the time variation of the light reflected from the scanned object, contains a direct current component. The amplification of this direct current component is, as has been stated, out of the question in any amplifier intended for continued operation over long periods of time. The requirements as to the range of frequencies to be transmitted, as discussed in the preceding section, make it necessary to provide a circuit having practically uniform efficiency from 10 cycles to above 20 kilocycles. The relative phase shift of the several components must also be kept very small. In view of the large amplification and consequent large number of stages necessary, it has been thought impracticable to use transformer coupling between all stages as the aggregate frequency and phase distortion might well be greater than could be tolerated. The so-called resistance capacitance coupling has therefore been used.

The arrangement of the several photoelectric cells in their cabinet, as shown in Fig. 3, is such that one amplifier can be connected directly to two of the cells leaving the third to operate a second amplifier. The outputs of these two amplifiers are then connected in parallel to the common battery supply equipment shown at the bottom of the two vertical cells.

By the use two stages of amplification in the photoelectric cell amplifier, the signal is brought to such a level that it may be carried by suitably shielded leads to other amplifiers outside the photoelectric cell cabinet. This permits using the convenient relay rack form of mounting. The signal level is, however, still low and may be adequately handled in amplifier units which differ but little from those used with the photoelectric cell.

The remaining requirements placed on the amplifiers at the transmitting terminal are those set by the telephone line. One of primary importance is that which determines the amount of energy needed. In order that the signal wave shall be of such magnitude that any interference present in the line may be negligible in comparison, it is desired that the alternating current delivered by the final amplifier stage shall be at least 4 milliamperes into an impedance of 600 ohms. The energy to be supplied is, therefore, approximately 0.01 watts, which determines the choice of the last amplifier stage. To build up the signal to a value sufficient to operate this output tube it has been found that eight stages of the small sized tubes and one stage of greater load-carrying capacity must be used. The total amplification given by these ten stages is approximately 130 T U. It is through this known gain of the amplifiers that we get our only accurate quantitative data as to the magnitude of the initial signal wave. This comes out to be about 10^{-15} watts or, with a 100,000 ohm resistance in series with the photoelectric cell, the potential available at the first tube is roughly 10 microvolts.

The characteristics of the line also determine the means by which it shall be coupled to the final amplifier stage. In order to secure the proper impedance matching and to prevent the line from being unbalanced with respect to ground, it was felt desirable to use transformers if possible rather than to attempt the design of a tube circuit capable of meeting the requirements directly. The problem included both output and input transformers, and specified an amplitude-frequency

characteristic constant to within ± 0.5 T U from 10 cycles to 25,000 cycles. The input coils intended for use at the receiving terminal had the additional requirement that a minimum of interference current should be induced in the secondary due to potentials between the line and ground. The success with which this problem

2. High ratio input transformer

pedances of 2000 ohms and 600 ohms when connected between generator and load circuits having these values. Curves 2 and 3 show the effective transmission gain of transformers having voltage step-ups of 6.5 and 2.5 respectively, when used to connect the first stage of the vacuum tube amplifier to a 600 ohm generator impedance. The envelope delay curves for the output transformer and for the high ratio input transformer are given in Fig. 23. Photographs of the coils are given in Fig. 24. A large factor in being able to get coils of this type lay in the availability of permalloy for the core material. The output transformer is connected to the amplifier through a blocking condenser in order to avoid possible saturation in the core due to the passage of direct current.

Measurements made on the several elements of the amplifier system have shown that its overall frequency characteristic is constant to within ± 2 T U from 10 to 20,000 cycles.

In an amplifier having as much gain as that just described it is apparent that a slight change in the potential of the power supply will cause a considerable change in the overall efficiency. Moreover variations

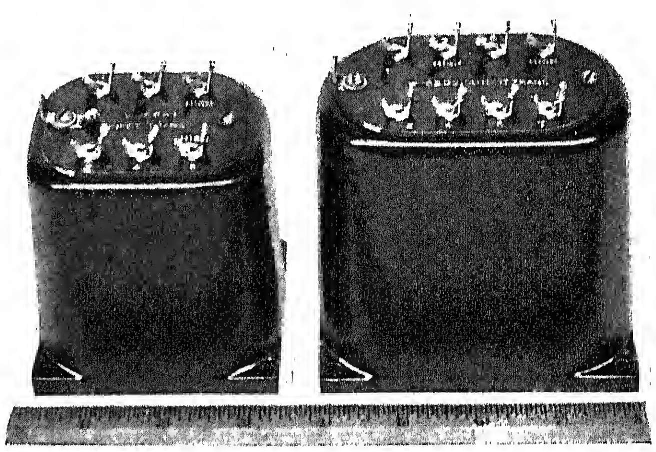

FIG. 24—TRANSFORMERS USED FOR COUPLING AMPLIFIER CIRCUITS TO LONG DISTANCE TELEPHONE LINES

in the intensity of the light source used with the scanning system will cause corresponding changes in the intensity of the initial luminous signal wave. To insure that the energy level supplied to the line is at all times of the proper magnitude a level indicator has been provided to permit continuous observations of the output of the amplifier. This consists of an amplifier-rectifier circuit so arranged that the space current of the last tube is a function of the alternating current voltage impressed on the first, being roughly proportional to the square of its amplitude. By means of a direct current milliammeter, therefore, it is possible to keep a very accurate check on the amplitude of the signal delivered to the line.

RECEIVING CIRCUIT

Coming now to the receiving terminal equipment we find that the signal wave which was delivered to the line at a power level of 10 milliwatts may, under some conditions, be reduced to a level 50 T U below this, or to 0.1 microwatt. It is, therefore, necessary first of

all to provide amplification to bring the signal to a level where it may operate the circuits controlling the illumination from which the image is to be reconstructed. In view of the fact that several types of receiving equipment are to be operated and also since the signal may be derived from any of several sources, either wire line, radio, or local transmitting station, it is desirable to fix some one energy level as a reference point and to bring all signals to this value so that they may be supplied interchangeably to the several receiving systems. A convenient reference level is that already set as the proper input to a telephone line, namely 10 milliwatts. At the receiving terminal, therefore, amplifiers have been provided which are similar to the final stages used at the transmitting terminal. These include units containing the small sized tubes and terminate in units identical with that supplying current to the line except that the output transformer is omitted. The first stage is, as mentioned in the preceding section, connected to the line through an input transformer. The amplifiers associated with the several incoming signals are each provided with a level indicator of the type already described. These terminal amplifiers and the several receiving circuits are all terminated in jacks, exactly like telephone circuits, and it is possible, therefore, to connect any receiving machine to any desired transmitting station simply by patching the proper jacks together, exactly as telephone circuits are connected at the central office.

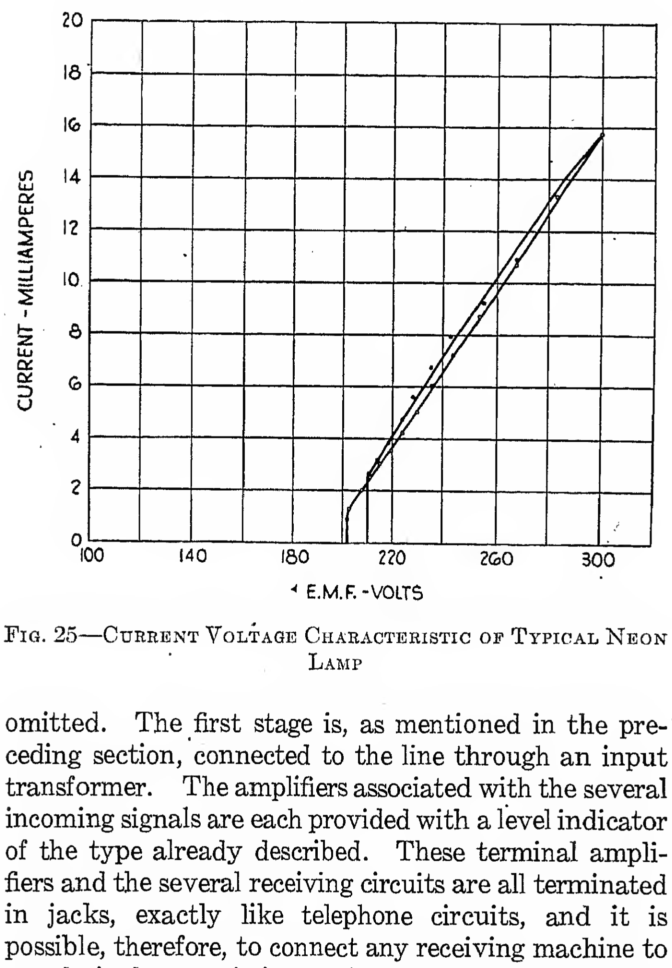

Fig. 25—Current Voltage Characteristic of Typical Neon Lamp

Before describing the final stages of the amplifier circuits it is necessary first to examine the properties of the light source which is to be controlled. In the case of the disk receiving machines described in the first section of this paper it is recalled that a single neon lamp is used having a rectangular electrode the entire area of which glows at each instant with an intensity proportional to the intensity of the initial luminous signal. The current voltage characteristic of a typical neon lamp is given in Fig. 25. It will be seen that no current flows until the voltage across the lamp reaches the breakdown potential which, in the example shown, is about 210 volts. From this point on the current increases linearly with respect to voltages in excess of a value somewhat below the breakdown point. It will also be seen from the curve that the value of current depends somewhat upon the direction in which the voltage is changing. In most cases, however, the function comes sufficiently close to being single valued for our present purposes. In view of the well established linear correspondence between the intensity of the illumination resulting from the glow discharge and the current, it is required to so arrange the circuits that the current through the lamp is at all times proportional to the illumination at the transmitting terminal.

It will be recalled that the electric signal wave as transmitted through the various amplifier circuits differs fundamentally from the initial luminous wave in that the direct current component has been eliminated. It is necessary, therefore, to restore this component before the changes in light intensity at the receiving terminal will follow those at the transmitting terminal. The several factors entering at this point may perhaps best be examined in terms of an elementary circuit such as given in Fig. 26. In this case the neon lamp is connected in series with the plate circuit of a vacuum tube and its polarizing battery. The circuit may be considered for the present as equivalent to one in which the neon tube is replaced by an ohmic resistance and in which the potential of the polarizing battery is reduced by an amount corresponding to the back e. m. f. of the lamp. Under these conditions the relation between current—and therefore illumination—and the voltage on the grid of the vacuum tube is as shown by the curve given with the figure. This curve takes into account the change in potential between the plate and filament of the vacuum tube due to the voltage drop in the lamp resistance. If the reactances in the circuit are negligible this curve may be taken as the dynamic characteristic of this portion of the system.

Let us assume that to properly build up the desired image at the receiving terminal the light is to be varied between the limits set by the two horizontal lines a and b. It is apparent that two adjustments are necessary in the grid circuit. The amplitude of the impressed alternating current must be such that the difference between its positive and negative maxima is equal to the difference between the grid voltages corresponding to these currents. This is taken care of by suitable adjustments of the amplification. It is further necessary that the bias introduced by the grid polarizing battery be such that the positive and negative peaks coincide with these same values of grid voltage. Under these conditions the grid battery must be looked

upon as supplying two absolutely distinct biases, one the bias for the tube and the other the bias for the signal. For example, if the signal wave as delivered to

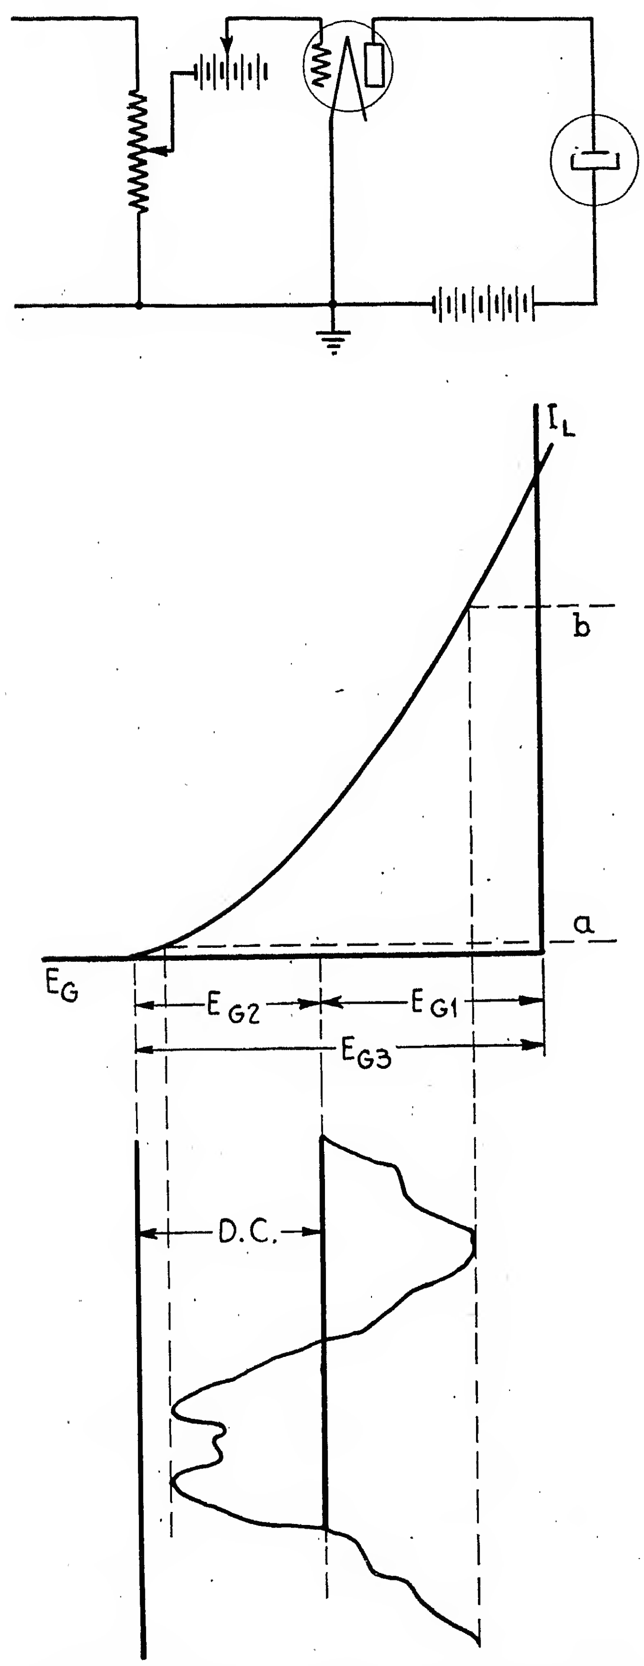

FIG. 26—CIRCUIT SCHEMATIC AND OPERATING CHARACTERISTIC OF NEON LAMP AMPLIFIER

the grid circuit contained the original d-c. component properly amplified, it would be necessary to adjust the system so that zero current would be obtained with no impressed signal. To accomplish this the tube would require the negative grid bias E_{G3}. Variations in signal voltage would then be considered as taking place about this value of grid potential as the origin. Thus E_{G3} is the operating bias of the tube. To properly locate the signal wave, however, it is necessary to add the positive bias E_{G2}. It will be seen from the curve that this bias corresponds exactly to the direct current component which is to be restored to the signal. The sum of these two biases, obviously, gives the actual bias, E_{G1}, with which the tube is operated.

In the circuit as shown the well-known curvature of the vacuum tube prevents us from obtaining a linear relation between the current through the neon lamp and the signal voltage. This condition may be overcome by a number of circuit modifications of which that shown in Fig. 27 is typical. Instead of connecting the neon lamp and the vacuum tube directly in series a resistance is provided across which is set up a potential, E_X, proportional to the current through it. Across this resistance is shunted the neon lamp and a biasing battery, E_B. The adjustment of this circuit is indicated by the curves shown. Curve *A* expresses the relation between the grid potential of the vacuum tube and its plate current. Curve *B* shows the relation between this same plate current and the voltage across the external resistance. When no current is flowing through the vacuum tube the potential of the biasing battery is insufficient to break down the neon lamp and no current flows through the circuit containing the neon lamp and the plate circuit resistance. As the current through the vacuum tube is increased from zero the total current flowing is that through the resistance branch. When, however, the potential drop across this resistance reaches such a magnitude that, together with the potential of the biasing battery, it is sufficient to break down the neon lamp, the latter will begin to draw current which thereafter increases linearly with further increases in the voltage, E_X, across the external resistance. The voltage across the neon lamp itself differs from that across the resistance by the amount of the battery E_B. The relation between the neon lamp current and the voltage across it, as given by Curve *C*, may therefore be plotted directly above the characteristic just discussed by displacing the vertical axis an amount corresponding to E_B. This amount is shown as E_{L1}. Here again we have two separate biases controlled by a single adjustment. The potential E_{L2} is fixed by the minimum plate current which can be taken from the tube without departing too seriously from the linear portion of the tube characteristic. It is, therefore, an operating bias of the circuit which is unaffected by any characteristic of the neon lamp. The latter, however, must be operated with a bias E_{L3} corresponding to its

effective back e. m. f. As in the case of the grid circuit bias just considered, the bias E_{L1} actually introduced into the circuit is the difference between these two independently determined biases.

By projecting values of lamp current horizontally

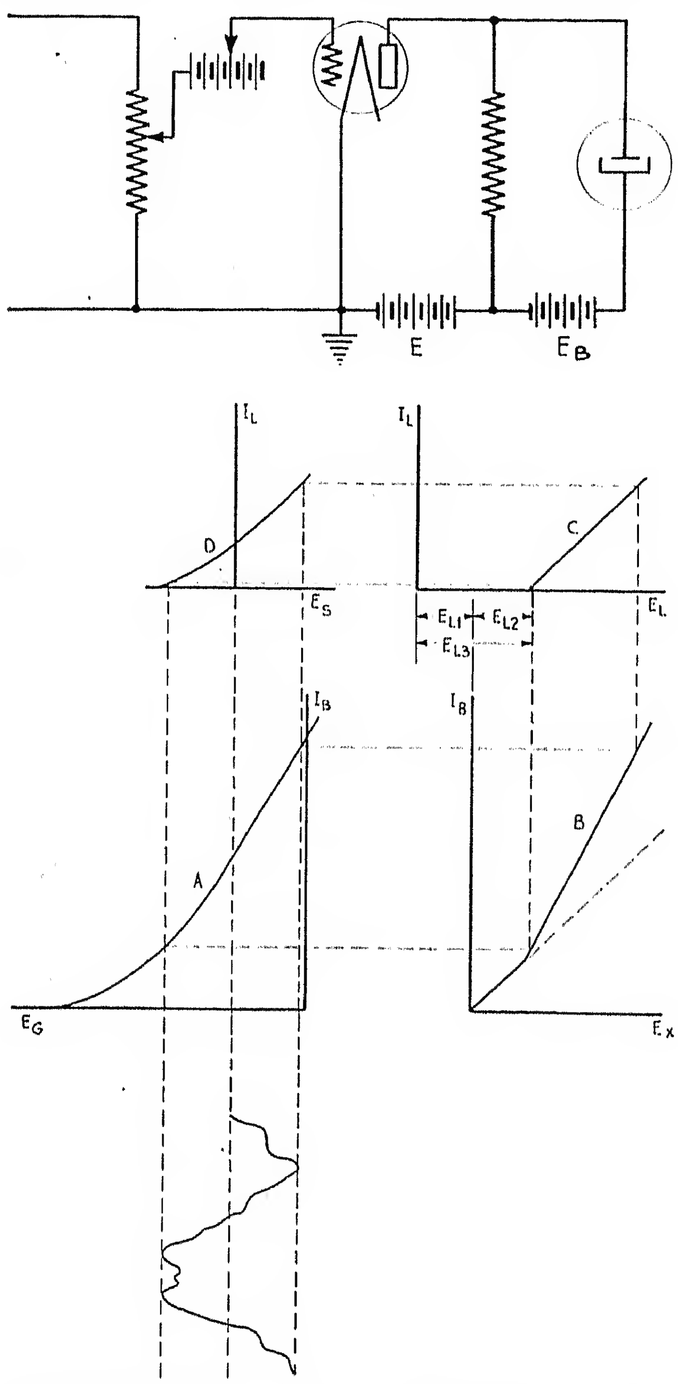

FIG. 27 CIRCUIT SCHEMATIC AND OPERATING CHARACTERISTICS OF CIRCUIT ARRANGED FOR LINEAR OPERATION OF NEON LAMP

and plotting their intersections with vertical projections through the corresponding grid potentials on the vacuum tube characteristic we obtain Curve D, which expresses the relation between the instantaneous value of the signal and of the current in the neon lamp as derived from the characteristics of the several elements of the circuit. Inasmuch as the intensity of the illumination is proportional to the lamp current it will be seen that we have approached the desired linear correspondence between the instantaneous values of the signal and of the light.

It will be noted that care has to be exercised to insure that the alternating current as impressed on the last vacuum tube is of the proper polarity. If it is not, the received image will be a negative instead of a positive. This may be controlled either by the connections to any one of the transformers or by the number of vacuum tube stages. With an even number of stages the polarity will be reversed from that given by an odd number. This is because an increase in negative potential on the grid of a vacuum tube causes a decrease in the space current and hence a decrease in the negative potential applied to the grid of the next tube.

In the case of the grid type of lamp with the individual external electrodes, the impedance to which energy must be supplied differs materially from that presented by the rectangular electrode lamp already described. For low voltages the impedance between any electrode and the central helix is effectively a capacitance of the order of 6 m. m. f. When, however, the voltage gradient in the interior of the tube becomes sufficient to break down the gas and cause a discharge to take place, the capacitance is increased to about 15 m. m. f. In fact, the tube may be looked upon as consisting of two capacitances connected in series. When the applied potential is sufficient to break down the gas and cause a glow discharge, that capacitance corresponding to the portion of the path inside the tube is effectively shunted by an ohmic resistance. The minimum discharge potential has been found to be independent of frequency over a wide range, but the current between electrodes is inversely proportional to the frequency because of the presence of the capacitance between the electrode and the glowing gas. Now, the brightness of the discharge is a function of the current sustaining it so that it becomes desirable to use high frequencies in order to get sufficient light without going to prohibitively high potentials. It is also desirable to operate at such a portion of the frequency scale that the percentage difference between the limits of the range shall be small, thus avoiding signal distortion due to the effect referred to above. There is, however, a definite upper limit to the frequency beyond which it would be impossible to operate because of the stray capacitances in the cable connecting the grid to the distributor. It has been found feasible to operate at a frequency of the order of a half million cycles.

The circuit problem, therefore, involves the production of a high frequency wave which varies in amplitude in accordance with the amplitude of the received picture signal. The solution has been conveniently obtained by using a radio broadcast trans-

mitter the voice frequency circuits of which have been so modified that the exteneded range of frequencies required might be handled with minimum distortion.

The envelope of the 500 kilocycle wave modulated by the picture signal, as shown in Fig. 28, is proportional to the signal amplitude plus a direct current biasing component of such magnitude that when the envelope reaches 160 volts the tube fails to light. This corresponds to a black area in the picture. When no picture signal is being received the amplitude of the unmodulated carrier wave causes the tube to light at average brightness, corresponding to the locally introduced d-c. component of the signal. It follows, then, that the amplitude of the unmodulated carrier is fixed, as in a previous example, by the joint requirements of

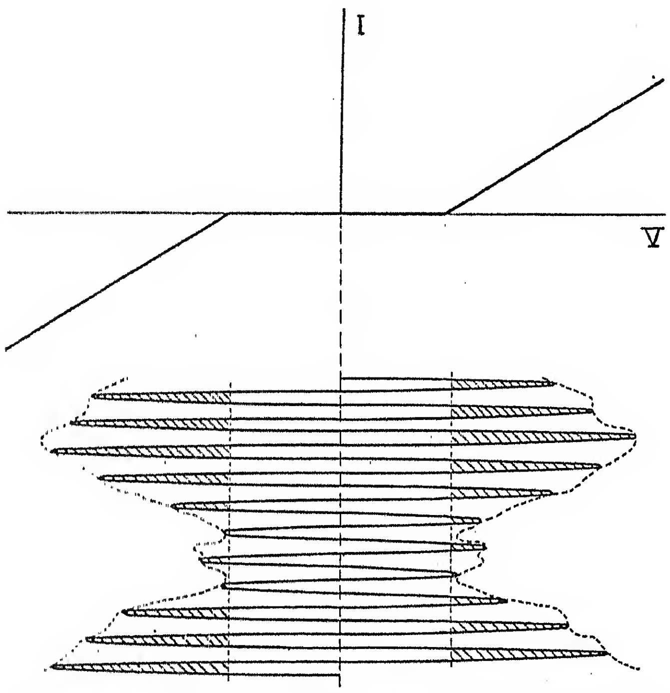

FIG. 28—DIAGRAMMATIC REPRESENTATION OF RELATION BETWEEN MODULATED HIGH FREQUENCY WAVE IMPRESSED ON GRID TYPE NEON LAMP AND LAMP CHARACTERISTICS. INTENSITY OF GLOW IS PROPORTIONAL TO SHADED AREA

two biases, that of the lamp and that of the signal bias.

There is a slight distortion inherent in this method due to the fact that the light, which is proportional to the shaded area of the curve of Fig. 28, is not strictly proportional to the amplitude of the envelope with respect to the 160 volt limit. This is, of course, because these peaks are portions of a sine wave and hence the time variation of the glow resulting from any given carrier cycle is a function of its amplitude. The effect is small, however, being most noticeable at low values of illumination.

In the case of the grid-lamp receiver the signal amplitude is adjusted, as for the disk receiver, by a potentiometer in the low frequency portion of the circuit. The carrier amplitude, however, is adjusted by varying the plate potential applied to the oscillating tube. The coupling to the lamp is made by connecting the central helix and the distributor brush across a portion of the condenser of the oscillating circuit.

The frequency-amplitude relation of the envelope has been made practically constant by employing resistance capacitance coupling in the signal input amplifiers, by providing extremely high inductance retard coils for the modulator—which is of the Heising type—and by inserting resistance in the oscillating circuit to provide sufficient damping. The relations between the original picture signal and the envelope of the high frequency wave, with respect to both amplitude and phase shift, were observed over the signal frequency range by means of a Braun tube and found to be satisfactory. The impedance of the connecting leads to the commutator was also measured and found to have a negligible effect on the frequency and damping of the oscillating circuit.

It has been found that there may be a lag between the time when the potential is applied to an electrode and the time when the gas breaks down. This is especially true following an interval during which there has been no discharge within the tube. Because of this those electrodes which are the first to be connected in any one of the parallel portions of the tube may fail to light. To overcome this effect a small pilot electrode is kept glowing at the left-hand end of each tube, thus irradiating the branch in such a way that the illumination of all electrodes follows immediately upon the application of potential. These pilot electrodes, which are obscured from view of the audience by the frame of the grid, are supplied by means of an auxiliary connection to the oscillator with a potential somewhat lower than that ordinarily impressed upon the picture segments.

Appendix I

The signal of Fig. 13 in the body of the paper may be represented as follows:

$$\left.\begin{aligned} f(t) &= 0 && \text{for } t < 0 \\ &= \frac{t}{T} && \text{for } 0 < t < T \\ &= 1 && \text{for } t > T \end{aligned}\right\} \qquad (1)$$

or by a Fourier integral in the form

$$f(t) = \frac{1}{\pi} \int_0^\infty d\,\omega \int_{-\infty}^{\infty} f(\lambda) \cos \omega\,(t - \lambda)\, d\,\lambda, \qquad (2)$$

where λ is an auxiliary variable of integration and ω is $2\,\pi$ times the frequency. To get the effect of sending this signal through a system which transmits all fre-frequencies without phase or amplitude distortion up to a cut-off frequency f_c it is only necessary to replace the upper limit of the first integral sign by N where $N = 2\,\pi f_c$. Thus:

$$F(t) = \frac{1}{\pi} \int_0^N d\,\omega \int_{-\infty}^{\infty} f(\lambda) \cos \omega\,(t - \lambda)\, d\,\lambda.$$

Then from (1):

$$F(t) = \frac{1}{\pi}\int_0^N d\,\omega \int_0^T \frac{\lambda}{T} \cos\omega\,(t-\lambda)\,d\,\lambda$$

$$+\frac{1}{\pi}\int_0^N d\,\omega \int_T^\infty \cos\omega\,(t-\lambda)\,d\,\lambda$$

$$= \frac{1}{\pi\,N\,T}\{\cos N\,t - \cos N\,(t-T)$$

$$+ N\,t\,[S\,i\,(N\,t) - S\,i\,(N\,t - N\,T)]\}$$

$$+\frac{1}{\pi}\Big[\pi + S\,i\,(N\,t - N\,T)\Big].$$

If we write $N\,t = x$, $N\,T = z$, and $\pi\,F(t) = y(x)$, then

$$y(x) = \frac{1}{z}\{\cos x - \cos(x-z) + x\,[S\,i\,(x)$$

$$- S\,i\,(x-z)]\}$$

$$+\frac{\pi}{2} + S\,i\,(x-z),$$

where

$$S\,i\,(x) = \int_0^x \frac{\sin x}{x}\,d\,x.$$

A series of graphs of $y(x)$ for different values of the product $N\,T$ is given in Fig. 15 in the body of the paper. These are generalized curves, the time scale depending on the particular value of cut-off frequency used. From these curves we can get the additional lag in the time, τ, in the rise of these curves over the original time T in Fig. 14.

Appendix II

Let $f(t)$ be the instantaneous intensity of the picture, and let it be represented by a Fourier integral;

$$f(t) = \int_0^\infty A(\omega)\cos[\,t\,\omega + \Phi(\omega)\,]\,d\,\omega. \qquad (1)$$

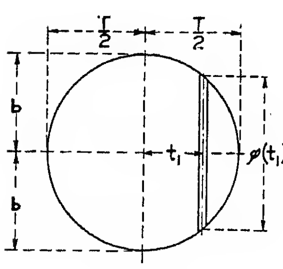

Fig 29

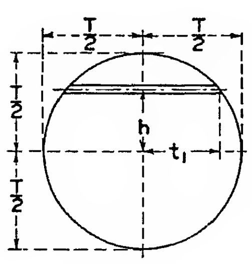

Fig 30

Analysis of the Aperture

Let T = time required for the aperture to pass a given point, Fig. 29.

Let $\varphi(t_1)$ be height of aperture at distance t_1 from its center.

The instantaneous amount of light passing through the aperture is

$$F(t) = \int_{t-T/2}^{t+T/2} \varphi(t_1)\,f(t_1)\,d\,t_1$$

$$= \int_{t-T/2}^{t+T/2} \varphi(t_1)\,d\,t_1 \int_0^\infty A(\omega)\cos[t_1\,\omega + \Phi(\omega)]\,d\,\omega$$

$$= \int_0^\infty A(\omega)\,d\,\omega \int_{t-T/2}^{t+T/2} \varphi(t_1)\cos[t_1\,\omega + \Phi(\omega)]\,d\,t_1. \qquad (2)$$

In the case of the rectangular aperture

$$\varphi(t_1) = \text{a constant} \qquad (3)$$

and, except for a negligible constant factor,

$$F(t) = \int_0^\infty A(\omega)\,d\,\omega \int_{t-T/2}^{t+T/2} \cos[t_1\,\omega + \Phi(\omega)]\,d\,t_1$$

$$= \int_0^\infty A(\omega)\left\{\frac{\sin[(t+T/2)\,\omega + \Phi(\omega)]}{\omega} - \frac{\sin[(t-T/2)\,\omega + \Phi(\omega)]}{\omega}\right\}d\,\omega$$

$$= 2\int_0^\infty A(\omega)\frac{\sin T\omega/2}{\omega}\cos[\,t\,\omega + \Phi(\omega)]\,d\,\omega. \qquad (4)$$

The transformation from $f(t)$ to $F(t)$ amounts merely to changing the relative amplitude of the Fourier components of $f(t)$ by a factor proportional to $\dfrac{\sin\,T\omega/2}{\omega}$.

In the case of the circular aperture we can divide the aperture up into narrow elements parallel to the direction of motion, as shown in Fig. 30. Elements at a distance h from the middle line of the strip have lengths

$$2\,t_1 = 2\sqrt{T^2/4 - h^2}. \qquad (5)$$

Each element considered as an independent *rectangular* aperture has the frequency characteristic

$$\frac{\sin t_1\,\omega}{\omega} = \frac{\sin\omega\sqrt{T^2/4 - h^2}}{\omega}.$$

The mean of all of these elementary frequency characteristics is

$$\frac{1}{T}\int_{-T/2}^{T/2}\frac{1}{\omega}\sin\Big[\,\omega\sqrt{T^2/4 - h^2}\,\Big]\,d\,h$$

$$= \frac{2}{T\,\omega}\int_0^{T/2}\sin\Big[\,\omega\sqrt{T^2/4 - h^2}\,\Big]\,d\,h$$

$$= \frac{1}{\omega}\int_0^{T/2}\sin\left[\omega\,T/2\sqrt{1 - \frac{4\,h^2}{T^2}}\right]\frac{2\,d\,h}{T}$$

$$= \frac{1}{\omega}\int_0^1 \sin\Big[\,T\,\omega/2\,\sqrt{1-x^2}\,\Big]\,d\,x.$$

$$= \frac{\pi}{2\,\omega} J_1\,(T\;\omega/2). \qquad (6)$$

where J_1 indicates a Bessel function of the first order.

In place of the amplitude variation function $\frac{\sin\,(T\;\omega/2)}{\omega}$ for the square aperture, we have $\frac{J_1\;(T\,\omega/2)}{\omega}$ as such a factor. From the very nature of the physical processes under consideration it follows that this average value of the elementary frequency characteristics is effectively the frequency characteristic of the aperture as a whole.

Synchronization af Television

BY H. M. STOLLER* and E. R. MORTON*

Member, A. I. E. E. Non-member

Synopsis.—*Synchronization of Television is the problem of holding two scanning disks so that their phase displacement is always less than four and one third minutes of arc. A 240 pole synchronous motor of the variable reluctance type is used as a basis. Coupled to it a direct current motor carries the steady component of the load. Hunting is eliminated by a condenser in series with the two synchronous motors whose capacitance is slightly less than that required to tune the circuit.*

As the motor might lock into step in any of 120 possible angular positions, only one of which would give the proper phase relations, a two-pole motor, with only one locking position, was provided by tapping the armature of the direct current motor at two points and bringing out the leads to slip rings. This was used for synchronizing while the 240 pole motor, connected [illegible], held the close synchronism required. The disks rotate at 1060 rev. per min. which gives 17.7 cycles on the two-pole and [illegible] cycles on the 240-pole motor.

For transmission the synchronizing current is attenuated to a level of 0.6 milliwatt and amplified at the receiving end. The 17.7-cycle current is an undesirably low frequency for transmission over telephone cables and so is used to modulate a [illegible]-cycle current through a polarized relay. This is demodulated at the receiving end, where a polarized relay by interrupting a local battery current gives a rectangular wave which acts through vacuum tubes on the field of the direct-current motor.

* * * * * *

THE problem of synchronization involved in television transmitting and receiving equipment is similar in principle to any synchronous motor problem but the requirements are of such a special nature that it is necessary to employ unusual features of motor design and control circuits to secure the required results.

General Requirements

At the transmitting end a scanning disk is employed containing 50 holes spirally spaced around the periphery of the disk rotating at a speed of 1060 rev. per min.[1] It is desired to rotate a similar scanning disk at the receiving end so that the hole through which the observer is looking at a neon lamp will be in a position corresponding to the hole which is transmitting light at the same instant at the transmitting end. Since there are 50 holes in each disk the holes will be spaced apart 7.2 degrees, thus 7.2 degrees of arc correspond at the receiving end to the width of the picture. Since the horizontal resolving power is approximately the same as the vertical (0.02 of the picture dimension) the arc occupied by a picture element is 0.02 X 7.2 or 0.144 degree. In order not to appreciably impair the quality of the picture, it is necessary to hold the synchronization within approximately ½ of the width of one element. This gives 0.144 degree divided by 2 or 0.07 degree as the requirement within which synchronization should be held. By way of comparison it might be mentioned that the angular twist in a length of 6 ft. of 1-in. steel shafting operated at rated load is of about the same order of magnitude.

An ordinary four-pole synchronous motor when operating at full load, unity power factor, has an angular phase displacement of about 20 electrical degrees between the impressed and back e. m. f. This corresponds to 10 mechanical degrees since the motor has two pairs of poles. If this motor is operated at constant load and the line voltage is varied the phase angle will decrease with increasing voltage or when the voltage is held constant and the load is varied, the phase angle will increase with increasing load. It is at once apparent therefore that the ordinary type of synchronous motor will not even approach the degree of precision required for the reason that any minute change in line voltage or load will cause variations in its phase angle of lag with respect to the impressed frequency of a far greater amount than 0.07 degree. Consider, however, a motor having 120 pairs of poles. Allowing 20 electrical degrees as the normal full load phase displacement this would be equivalent to 20 divided by 120 or 1/6 degree mechanical phase displacement. Even this amount is over twice the required permissible displacement of 0.07 degree. Since the variation of the phase displacement is the important factor and not the absolute amount of displacement, it is evident that if the line voltage and load are held reasonably constant a synchronous motor with 120 pairs of poles should be sufficiently precise.

Another requirement in addition to close phase synchronization is regulation of the acceleration or deceleration of the generator at the transmitting end. Such regulation is required due to the fact that an appreciable time is taken for the transmission of the synchronizing current a distance of 220 miles (circuit length) between New York and Washington. The velocity of propagation over the cable was approximately 19,000 miles per second while that of the picture on the open wire of 285 miles circuit length was about 175,000 miles per second, the corresponding times of transmission being 0.0116 second and 0.0016 second leaving a difference of 0.01 second approximately. Since the total permissible error in synchronization is

*Both of the Bell Telephone Laboratories, Incorporated, New York, N. Y.

1. This speed was determined by transmission considerations and is discussed in the companion paper by Messrs. Gannett and Green.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

0.07 degree it is reasonable to allow 0.02 degree as error due to acceleration regulation. Let a be the acceleration in degrees per second per second. Substituting in the formula $s = \frac{1}{2} a t^2$ gives $0.02 = \frac{1}{2} a (.01)^2$ or $a = 400$ degrees per second per second or a little over one revolution per second per second. For comparison

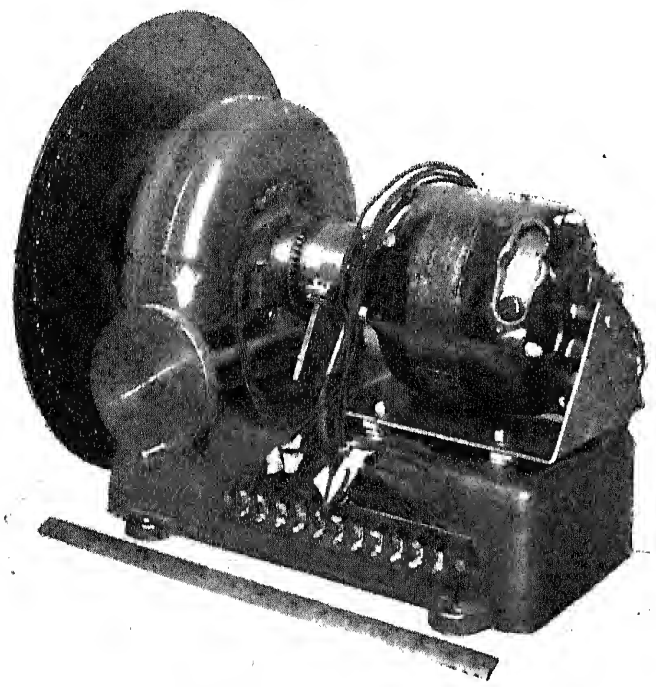

Fig. 1—Assembled Motor

consider a ¼ hp. unregulated shunt motor. If the line voltage increases 10 per cent it will cause an increase in speed from 4 per cent to 8 per cent depending on the magnetic saturation in its field circuit. This increase in speed will take place in a half second or more depending upon the moment of inertia of the load. Thus the acceleration in the case of a 1060 rev. per min. speed would be much greater than one revolution per second per second.

Since this problem of speed regulation is a separate one from that of the synchronization the description of the regulating circuit is taken up later on.

Motor Design

In accordance with the phase displacement requirement as explained previously it was decided to build the synchronous motors with 120 pairs of poles, thus giving a frequency of 2125 cycles at 1062.5 rev. per min. which was the exact speed finally employed. For the sake of mechanical simplicity these machines were made of the variable reluctance type which gives one cycle per rotor tooth thus requiring 120 teeth. The variable reluctance construction also simplifies the coil arrangement, the machine having only eight armature coils instead of a separate coil for each tooth. Fig. 1 shows a photograph of the assembled motor and Fig. 2 an inside view of the stator and rotor.

In the preliminary experimental work two of these machines were directly connected (Fig. 3) permitting either machine to act as a synchronous motor loading down the other machine. Each machine was driven by a shunt d-c. motor having inherently poor regulation, the d-c. motors furnishing the power and the a-c. machines transferring the variations from one d-c. machine to the other to hold synchronism in a completely two-way system. As was to be expected, it was found that the motors hunted badly at a frequency of about four cycles per second. In other words, instead of holding within a fixed electrical phase angle of 20 degrees the receiving motor oscillated throughout a phase angle of about $\pm$ 20 electrical degrees. This, of course, made the picture wabble back and forth across the aperture and was therefore unsatisfactory.

The ordinary method of preventing hunting by means of copper bars embedded in the pole faces was not practical on account of the large number of poles and limited space. The hunting trouble was cured by employing a series condenser between the motors using a value of capacity somewhat less than that required to tune the circuit. A rigid analytical treatment of this anti-hunting circuit is beyond the scope of this paper but its operation depends in general upon the curvature of the tuning curve due to the variation of the inductance of the machine with phase displacement. Since the condenser operates on the total inductance of the circuit, it is desirable to make the natural periods of oscillation of the two motors different. Otherwise

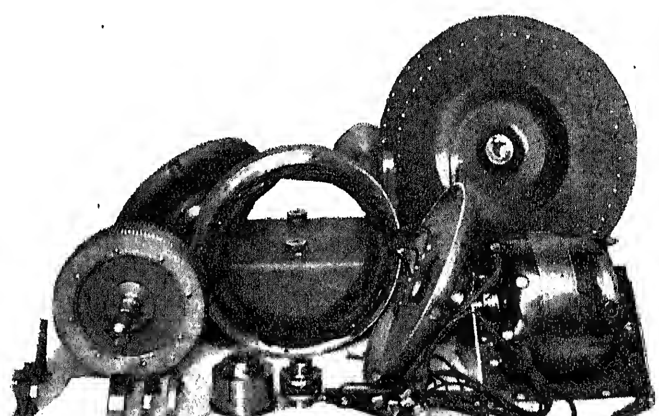

Fig. 2—Motor Disassembled

a decrease in the inductance of one machine may be accompanied by a simultaneous and equal increase in the inductance of the other thus leaving the total inductance unchanged and preventing the condenser from functioning. This was done by making one disk substantially heavier than the other.

The series condenser also neutralizes the greater part of the internal reactance of the motors thereby increasing the steady state torque.

Framing of Picture

There was still one unsatisfactory feature in this system in that the motor at the receiving end could interlock in any one of 120 different angular positions whereas in order to get proper framing of the picture it must be synchronized at a particular angular position. For example, if the disk at the receiving end is exactly 180 degrees out with respect to the disk at the transmitting end the observer will see the lower half of the picture on top; a dark space representing the dividing line between pictures and the upper half of the picture at the bottom. Similarly, if the disk is 90 degrees out at the receiving end the lower quarter of the picture will appear on the top and the upper three-quarters of the picture on the bottom. The disk at the receiving end may be brought into correct angular position by providing means for turning the entire motor through the necessary angle. It was found, however, that the

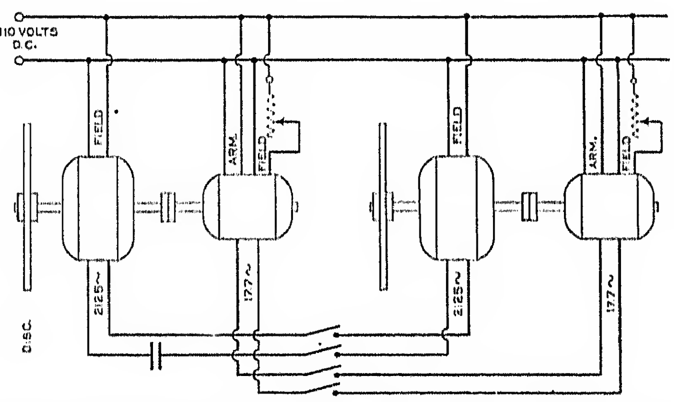

Fig. 3—Synchronization System Over Short Wire Line

rate at which the motor can be turned was limited by the fact that if it were rapidly turned it would throw the motor out of step.

As an aid to framing, therefore, a second two-pole low frequency interlock was added to the system by providing the d-c. motors on each end with a pair of slip rings tapped to two opposite commutator bars. The d-c. shunt motors thus acted as converters furnishing 17.7 cycles at 1062.5 rev. per min. With this added feature on both the transmitting and receiving motors the process of synchronization was first to close the 17.7 cycle circuit and adjust the field rheostat of the receiving motor until it came into step. Since this was a two-pole circuit there was only one angular position at which synchronization could occur. The high frequency synchronous machines were then connected together, thereby limiting the phase displacement to within 0.07 degree, as previously described. The high frequency motors in this system take the variation in load while the low frequency motor takes care of the steady constant component of load. Incidentally the addition of the low frequency synchronous motors greatly facilitated the synchronization of the high frequency motors inasmuch as it insured the proper initial speed. When the high frequency switch was closed there was merely a slight shift in phase angle to bring the receiving motor into step. The schematic circuit of the system thus far described is shown in Fig. 3.

Synchronization Over Long Lines

The above description explains the action of the synchronization system over lines of negligible impedance. In order, however, to secure similar results over a long distance telephone line or radio channel it is necessary to first attenuate the high and low frequencies to a power which can be safely applied to the transmitting end of the line and then amplify the power at the receiving end to restore it to the proper level. Fig. 4 shows the complete system employed.

While the high and low frequency machines on the transmitting end could have been designed so as to produce exactly the right power level it was desirable, for the sake of interchangeability, to build the transmitting and receiving motor equipment of the same size. The output from the transmitting high frequency generator (shown in Fig. 2) when untuned was approximately 17 volts at 2125 cycles. By means of a network this output was cut down to a level of 1 milliampere into 600 ohms impedance, the output impedance also being 600 ohms. This is a satisfactory level at which to transmit the high frequency, without inducing noise in adjacent wires in the telephone cables.

In the case of the low frequency interlock it was undesirable to attempt to transmit 17.7 cycles over a long distance line. The 17.7 cycles was therefore used to operate a polarized relay, the contacts of which modulated the ouput of a 760-cycle electro-mechanical oscillator[2] as shown in Fig. 6. In other words, the relay short-circuited the output of the oscillator alternate half cycles before application to the telephone line. Instead of using separate telephone pairs for the 2125-cycle and the modulated 760-cycle current, the two were combined by passing them through the line filter (shown in Fig. 7) thereby requiring only one pair for transmission of both frequencies. An identical network was employed for the radio channel. The problem of transmission of the synchronizing current is covered in the paper by Messrs. Gannett and Green and in the case of radio transmission in the paper by Mr. Nelson.

Receiving and Amplifying Circuits

Passing over this part of the problem, therefore, assume that the synchronizing currents have been

2. Described in the Bell Laboratories *Record*, March 1927.

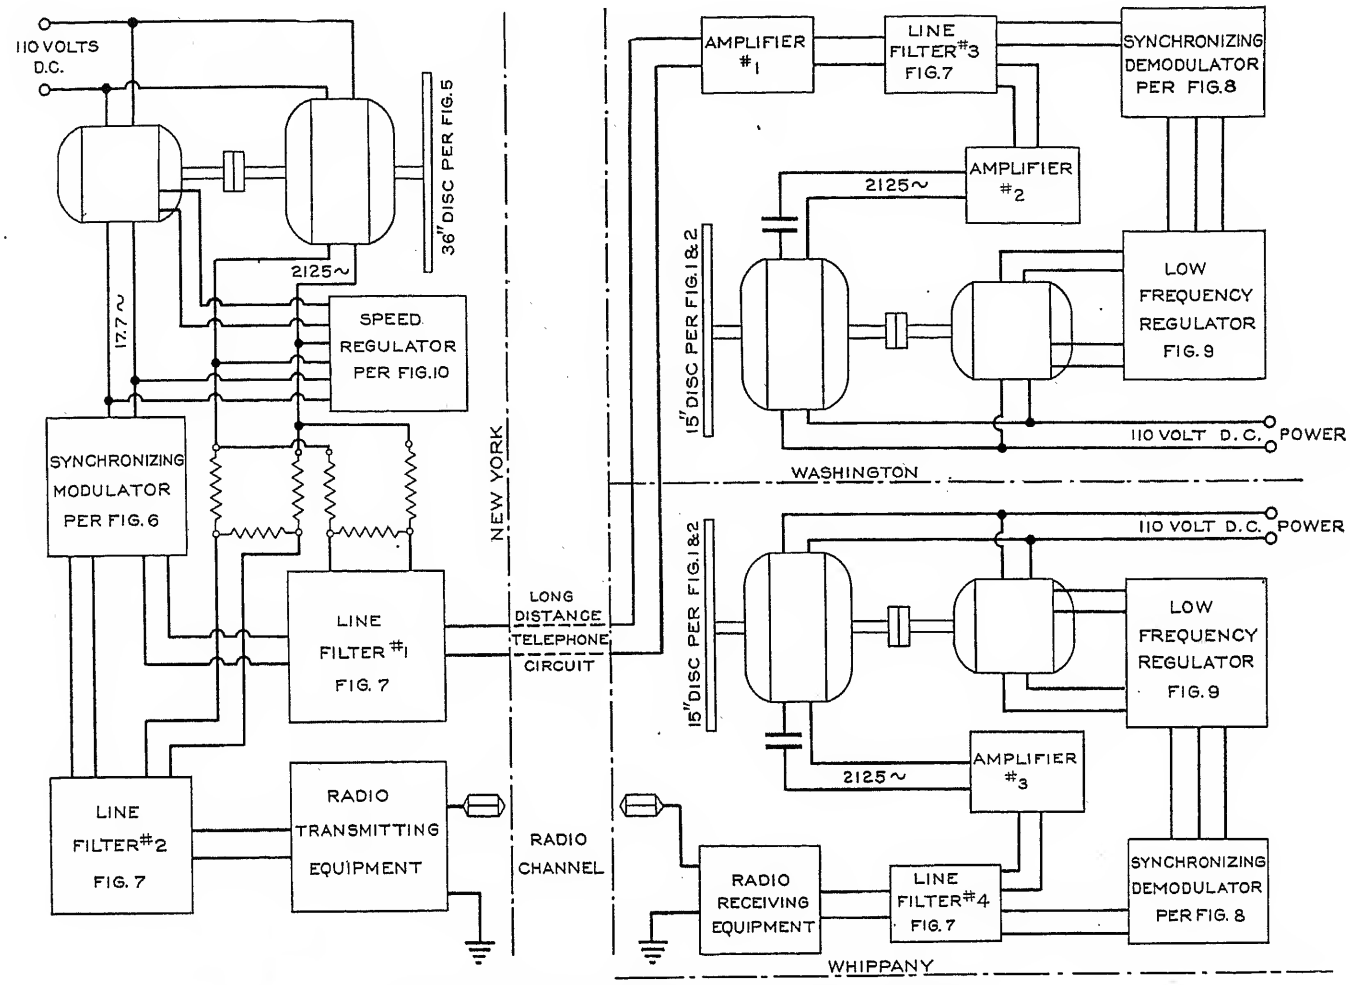

FIG. 4—COMPLETE CIRCUIT OF SYNCHRONIZING SYSTEM

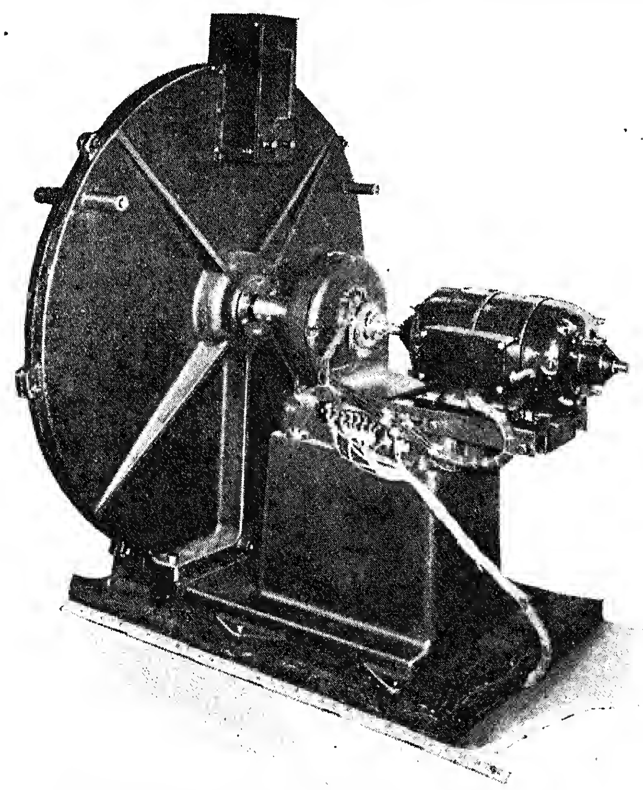

FIG. 5—LARGE SCANNING DISK MOTOR

obtained at the receiving end of the line. This power was delivered at a very low level being about 0.3 of a milliampere into 600 ohms impedance, or 50 microwatts. It was then given a preliminary stage of amplification (Amplifier No. 1 Fig. 4), passed through the line filter No. 3 (Fig. 7) and separated into 2125 cycles and 760 cycles modulated at 17.7 cycles. The 2125 cycle component was then amplified by two stages of amplification (amplifier No. 2) ending in push-pull 50 watt tubes and applied to the high frequency motor. These amplifiers being of the standard type are not described. The terminal voltage on the output coil of the amplifier was made greater than that of the high frequency motor so that the power flow was normally from the amplifier to the motor. The anti-hunting condenser was retained between the amplifier and the motor.

In the case of the low frequency circuit the output from line filter No. 3 was received in the form of 760 cycles modulated at 17.7 cycles. This was passed through the demodulator (Fig. 8) which operated a polarized relay whose armature opened and closed its contacts at 17.7 cycles per second. The contacts of the relay provided square-wave low frequency current by interrupting power from a local battery source. On account of the limited power output which the vibrating

contacts could safely handle without sparking it became necessary to amplify this low frequency output. While this would have been possible by the use of ordinary amplifier circuits it was found preferable from the standpoint of economy of apparatus to apply the low frequency regulation through a field circuit of the receiving motor. Referring to Fig. 9 it will be noted that the plate circuit of the regulating tubes is supplied

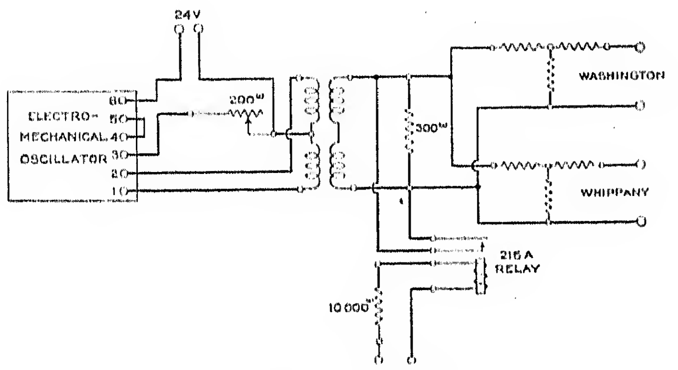

FIG. 6 SYNCHRONIZING MODULATOR

from the secondary of the transformer which is connected to the slip rings of the motor, while the grid circuit of these tubes is supplied with low frequency, low power 17.7 cycles from the contacts of the relay. As the motor is started up from rest the shunt field is weakened until the motor falls in step. At this point the frequency of the plate supply to the regulator tubes is identical with that supplied to the grids. If the phase relationship is such that the plates go positive at the same time that the grids are positive then the space current of the tubes is increased and the regulating field (which is an aiding auxiliary field) is strengthened, thereby preventing a further rise in the speed of the motor. In other words, for each combination of load and line voltage there is an equilibrium

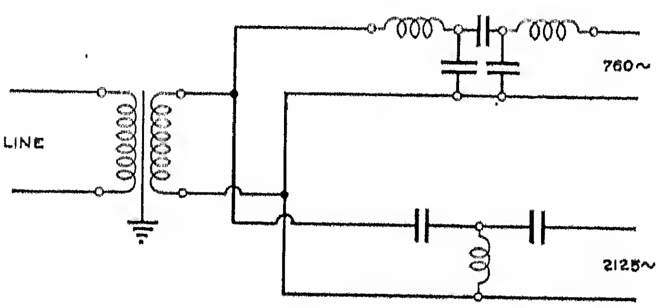

FIG. 7—LINE FILTERS FOR SYNCHRONIZING FREQUENCIES

phase position between the plate and grid voltages at which the corresponding regulating field current maintains the speed at the desired value.

MOTOR OPERATION

In actual operation the procedure was to first synchronize on the low frequency, and then on the high frequency circuit. The precise framing of the picture was then adjusted by rotating the motor by means of worm gearing through the necessary angle to center the image properly in the aperture. The high frequency current was of the order of 1.5 amperes at 2125 cycles with a terminal voltage of 100 volts at the high frequency motor. The power taken by the d-c. motor was approximately 0.8 ampere at 110 volts. The current through the regulating field controlled by the 17.7 cycle circuit was of the order of 20 to 40 milliamperes at 100

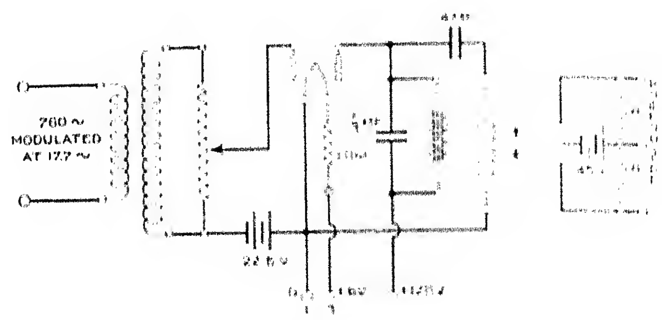

FIG. 8 SYNCHRONIZING DEMODULATOR

volts depending upon the phase position at which interlock occurred. It was found preferable to cut off the low frequency interlock feature after synchronization and framing had been obtained in order that irregularities in the time of contact closure of the relay might not produce changes in field strength of the d-c. motor which in turn would cause irregularities in power output. Such irregularities would give rise to phase shifts in the high frequency machine thereby producing unsteadiness of the picture.

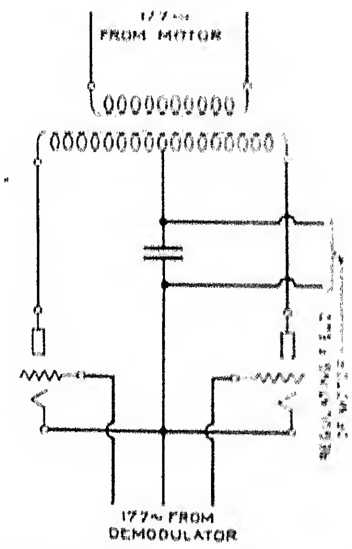

FIG. 9 LOW FREQUENCY REGULATOR

OPERATION ON RADIO CHANNEL

In the case of transmission of the synchronizing current by radio instead of by wire the same apparatus is employed except that it was found necessary to use a much higher value of high frequency current in order to hold the high frequency motor in step, the current being approximately 4 amperes as compared to 1.5 amperes

in the case of the other motors. This greater current was found to be necessary in order to hold the motor in step within the necessary phase angle of displacement, in spite of various types of interference picked up by the radio receiver, and associated circuits. This was mainly inductive interference from the picture and speech transmission sets arising from the fact that the synchronizing current was transmitted from New York to Whippany and picked up on a receiving set there whereas the picture and voice current was transmitted from Whippany to New York. A certain amount of interference was also encountered from ship spark sets and static.

Speed Regulation of Transmitting Motor-Generator

As previously explained under "General Requirements" the essential requirement of the speed regulator at the transmitting end is to limit the acceleration to about one revolution per second per second, over intervals as small as 0.01 second. The ordinary type of centrifugally operated vibrating contact regulator keeps the motor continually accelerating and decelerating between an upper and lower speed limit and while such a system could theoretically be employed if the flywheel were made large enough, it was obviously preferable to employ a type of regulator in which the speed was inherently held constant without such acceleration and deceleration.

The regulating circuit employed is shown in Fig. 10. The complete theory of this regulating circuit is to be covered in another paper to be presented before the Institute. Briefly the principle consists in employing a sharply tuned circuit as the primary speed controlling element resonating at a frequency slightly less than the frequency at which the machine is operated. A voltage from the high frequency generator is applied to this tuned circuit and thence to a detector tube which in turn operates on the grids of a pair of push-pull regulator tubes; these tubes controlling an auxiliary regulating field winding on the motor. The circuit also contains anti-hunting means, the theory of which will be given in the later paper. Instead of applying this regulating circuit to the small 15 in. scanning disk motor shown in Fig. 3, it was decided on account of its greater flywheel effect to use the large 36 in. disk shown in Fig. 5 which was used for receiving the picture at New York. It therefore became the transmitter from the synchronizing standpoint for all of the other units although from the picture standpoint the big disk acted as a receiver.

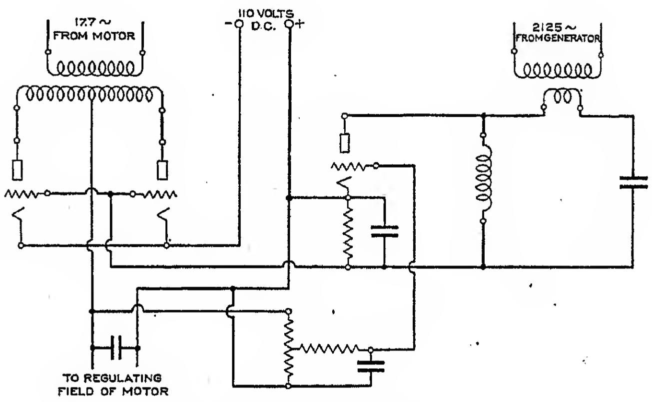

Fig. 10—Speed Regulator

Local Stations

In addition to the stations at Washington and Whippany there were three local stations in New York employing similar high and low frequency synchronous motors with 15 in. disks. These were controlled in the same manner except that first stage of amplification and the line filters were omitted. One station was employed for monitoring purposes, another operated a local transmitter, while the third operated the big grid receiver seen by the entire audience.

Wire Transmission System for Television

BY D. K. GANNETT*

and
E. I. GREEN*
Associate, A. I. E. E.

Synopsis.—This paper deals with the transmission problems which were met and solved in connection with providing wire circuits from Washington to New York for thet elevision demonstrations which took place on April 7, 1927 and following. For transmission of the television images a single transmission channel was set up combining the frequency ranges usually assigned to telegraph, telephone, an dcertain carrier channels. The special line requirements were met so successfully that the television images transmitted from Washington were indistinguishable from those transmitted locally.

Introduction

A SYSTEM of television, to be worthy of the real meaning of the name, must be capable of operation over a considerable distance. Spanning this distance, there must be a connecting medium suitable for faithfully transmitting the television currents. This paper describes how the connecting medium was provided between Washington and New York for the recent television demonstrations,[1] by adapting to this purpose existing wire facilities of the Bell System.

Fortunately, wire facilities of the type which were available between Washington and New York had been utilized for some time to transmit simultaneously many telephone and telegraph messages, involving a frequency range more than ample for the television requirements, so that the transmission characteristics of the lines throughout the necessary range of frequencies were well known. The matter of providing a suitable channel to carry the television currents consisted, therefore, in throwing together the frequency ranges which had heretofore been utilized for providing a number of separate telephone and telegraph channels. In addition to providing this very wide band communication channel it was necessary to apply special distortion-correcting networks so that the overall channel would possess proper characteristics and also to take care to avoid introducing disturbances due to such things as line irregularities, noise, etc.

Due to the perfection of the transmission methods which were utilized, it was found that when the circuit was first established, in accordance with the requirements which had been deduced, the television images transmitted from Washington were indistinguishable in quality from those transmitted locally, this result being secured without any deviation from the adjustments which had been worked out in the original design.

Requirements

General. The ideal requirement for a transmission line for television, or for that matter any other purpose, is, of course, that it introduce no distortion whatsoever, in which case there could be no question but that the television images obtained in the receiving apparatus after transmission over the long distance line would be identical with the image obtained with the transmission only over a distance of a few feet. Practical transmission lines, however, tend to introduce a certain amount of distortion and the less the allowable distortion which is specified the greater will be the cost of providing a proper line. Before going ahead with the matter of engineering the line required to transmit the television currents from Washington to New York it was, therefore, first necessary that the requirements be set. The requirements were made more severe than strictly necessary in cases where they were easy to meet.

Frequency Range. In any system for the electrical transmission of intelligence, the required frequency range is, in general, proportional to the speed of transmission. In the case of picture transmission or television, the speed of transmission may be expressed in terms of the number of picture elements which must be transmitted per second, where a picture element is the smallest unit area which it is intended to be able to distinguish in the received picture from its neighboring unit areas.

When the picture currents are transmitted in the most efficient manner the frequency range necessary is approximately equal to half the number of picture elements which must be transmitted per second. A simple way of seeing this is to realize that as the picture elements are transmitted in sequence, the greatest possible rate of variation of detail is obtained when alternate picture elements are black and white. A complete cycle corresponds in this case, therefore, to the time interval required to transmit two picture elements.

According to this relationship this particular television system in which about 40,000 picture elements per second are transmitted should require a frequency range of approximately 20,000 cycles. As a matter of fact it was found by a laboratory test that due to certain characteristics of the apparatus a frequency range as great as this was ample, just detectable distortion being introduced in the reproduction of the human face when the range was narrowed to about 14,000 cycles. In providing the line circuit, however, extending the frequency range to 20,000 cycles involved so little

difficulty that it was decided to provide this very liberal frequency range.

In the particular television system which has been described the very low frequencies (below about 10 cycles) are suppressed. It was, therefore, not necessary that the line transmit these very low frequencies. The frequency range which the line should transmit was accordingly set as 10 cycles to 20,000 cycles.

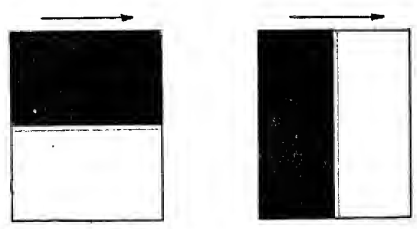
Attenuation. Referring to still picture transmission, it has been found that variations of attenuation with frequency of several transmission units do not appreciably impair the quality of the picture. Since no great difficulty was anticipated in meeting closer limits, however, it was decided to set the limits for the variation of attenuation with frequency at $\pm$ 2 T U within the frequency range of 10 to 20,000 cycles.

Phase Characteristics. A characteristic of wire lines, whose importance has been increasingly realized in recent years, is their phase characteristic. In speech transmission, transients due to unequal velocity of the different frequency components have been found to be an important consideration on some types of lines. In picture transmission and television, also, it is important that this phase distortion be controlled, as otherwise the image might be blurred due to the arrival of the various frequency components at different times. The type of transient which has been found to impair the quality of pictures is the type which is relatively rapid and the aim has been to make the phase characteristics such that those transients would be small.

The requirement with respect to phase for distortionless transmission is that $\frac{\beta}{\omega}$ be a constant where β is the phase change in radians for the entire circuit, and ω is equal to 2π times the frequency. $\frac{\beta}{\omega}$ is known as the "phase delay" or the steady-state time of transmission. $\frac{d\beta}{d\omega}$ is the time required for the transmission of the envelope of a wave whose components center closely about the frequency $\frac{\omega}{2\pi}$ and it will be referred to as the "envelope delay." Since it is more convenient to measure the envelope delay the requirements were set up in terms of this quantity. When $\frac{\beta}{\omega}$ is constant it is evident that $\frac{d\beta}{d\omega}$ is also constant. While the converse of this is not in general true, the conditions as actually encountered were such as to permit its use as a measure of the small variations involved.

The envelope delay characteristics of a number of circuits, which have been found to give varying degrees of transient on still pictures, have been measured. Also data were available from tests of picture transmission through filters and other networks whose delay characteristics were known. From these various data, the permissible deviations of the delay characteristic for still picture transmission were determined, and dividing these figures by 50, the ratio of the rate of transmission in picture elements per second in the two cases, the limits for the television circuits were obtained. In this way it was decided to attempt to keep within $\pm$ 10 microseconds, if possible, with outside limits of $\pm$ 20 microseconds. Check tests of these limits were made with the television apparatus in the laboratory by transmitting the currents through various known networks, and noting the effect on the received image.

Unlike the attenuation requirements, the delay requirements for television are not the same over the entire frequency range, but are much more lenient in the lower frequency range, as was shown by experiments in the laboratory. A physical picture of the reason for this may be obtained by reference to Fig. 1.



Arrows Show Direction of Motion of Light Spot
A B

Fig. 1

Fig. 1A shows a picture placed in position before the sending machine, consisting of a piece of cardboard the same size as the image-area which can be transmitted, the upper half of the cardboard being colored black, while the lower half is white. As has been explained in the paper by Messrs. Gray, Horton, and Mathes, the picture is scanned by a spot of light which moves from left to right in successive lines, tracing 50 horizontal lines across the picture in one-sixteenth of a second. The first 25 of the lines lie on the black and the remaining 25 on the light part of the picture. The process is repeated 16 times per second, each repetition of 50 lines giving one complete cycle of black and white. The frequency components in this case are multiples of 16 cycles. A transient which blurs the picture outline over a given number, n, of picture elements (downwards) corresponds to a time interval equal to the time of tracing n lines, *i. e.*, $\frac{n}{800}$ second.

Now consider Fig. 1B. Here the picture has been

rotated 90 degrees. In this position, a complete cycle of black and white is obtained with each line instead of with each 50 lines. The frequency components in this case are multiples of 800 cycles and bear the same relations to 800 cycles as the components spoken of above bear to 16 cycles. A transient which blurs the picture outline n picture elements (horizontally, this time) corresponds to a time interval of n forty-thousandths of a second. Evidently the delay requirements are 50 times more lenient in the former case than in the latter so that the delay requirement at the highest frequencies, which determine the fine detail in the direction of scanning, is 50 times as severe as at low frequencies, which determine the fine detail in a direction perpendicular to the direction of scanning.

In the still pictures referred to, the transients extended in the direction of travel of the light spot and there were no transients analogous to those discussed here in connection with Fig. 1A. For this reason the delay limits determined from still picture transmission are the ones which apply to the higher frequencies. For the lower frequencies the requirements are obtained by multiplying the high-frequency requirements by 50. For these reasons, together with the result of a Fourier analysis of the picture current, the limits were set at ± 10 or ± 20 microseconds from 400 to 20,000 cycles. Below 400 cycles, the departures from the constant delay were permitted to be ± 500 or ± 1000 microseconds.

Noise. Another important requirement is that relating to the ratio of the picture currents to the extraneous interfering currents which may arise in the line from power induction and other sources. Early experience with the television apparatus showed that considerably more noise was permissible in the case of television than in the case of still picture transmission so that in this case comparison with the still picture transmission would result in an unduly severe requirement. This is thought to be explained by the fact that in the case of television the pictures are flashed before the eye 16 times per second and the effects of the extraneous currents occur on successive flashes in different positions, so that defects of one flash are corrected on the next.

A set of experiments was performed from which it was determined that if the ratio of average picture currents to average noise currents exceeded about 10 the results were satisfactory. In order to assure considerable margin above this figure, it was decided to make the average television current to be transmitted into the line 4 milliamperes.

Echoes. If two paths exist by which the currents may travel from the sending point to the receiving point, the length of the two paths being different, a double image will be produced on the received picture, forming what may be termed visual echo. In the case of telephone lines, the echoes may exist on account of reflections between impedance irregularities in the circuit so that the currents arrive at the receiving point both by way of the direct transmission path and by way of a transmission path which includes an extra loop between two irregularities. If the echo is not greatly attenuated with respect to the main transmission, the result may be quite disturbing on the received picture. It has been found by experiment that the echo is too weak to be seen if it is more than 25 T U weaker than the main current and, accordingly, care was taken in setting up the New York-Washington circuit to avoid introducing echo paths of lower equivalent than this.

General Choice of Method

Two general methods are possible for transmitting the currents over the line circuits. One method is to transmit the currents directly without change of frequency. This method involves the transmission of the currents of the frequency range determined upon above, namely, from about 10 cycles to about 20,000 cycles per second.

The other general method is the carrier method, in which the television currents modulate a carrier current of suitable frequency and are thereby moved to another portion of the frequency spectrum prior to transmission over the line. At the receiving end of the line the carrier currents are then restored to the original frequencies of the television currents.

Several different schemes of carrier transmission are possible. The simplest is to modulate a carrier with the television currents and to transmit both side bands. This has the disadvantage of requiring the transmission of twice as wide a frequency range as that occupied by the original television currents. Another scheme is to transmit a single side band. A third possible scheme is to transmit both side bands for the lower frequencies and only one side band for the higher frequencies.

One advantage to be secured by the carrier method is that it lessens the severity of some of the line problems through avoiding the transmission of very low frequencies over the line circuit. At these frequencies the amount of noise found on lines is usually considerably greater than at the higher frequencies.

After weighing the relative merits of the carrier and direct transmission methods it was decided to make use of the latter because of its simplicity. An important factor in this decision was the successful development, for use in connecting the apparatus to the lines, of transformers providing adequate transmission of the entire frequency range from 10 cycles to 20,000 cycles.

Arrangements for Television Circuits

Line Layout Between New York and Washington. The layout of the wires between New York and Washington is shown in Fig. 2. The circuit over which the

waves actually carrying the pictures were transmitted (marked Picture Circuit) consisted principally of a pair of copper wires 165 mils in diameter. At a number of places on the route the circuits were carried in cable as indicated in the figure. The total length of the television circuits was about 285 miles, of which 8 miles consisted of cables and the remainder of open wire.

Transpositions. As the circuits employed were originally designed for voice-frequency operation only, except for a section at the New York end, it was necessary to add transpositions to them to prevent interaction with adjacent circuits at the high frequencies involved in the television transmission. The high-frequency currents were thus prevented from passing over into the adjacent circuits which would have resulted in irregularities in the attenuation, line impedance, and phase shift characteristics of the circuit.

Incidental Cables—Loading. Any appreciable length of non-loaded cable included in an open-wire television circuit has certain very objectionable effects. The impedance irregularities introduced by the cable destroy the uniformity of the line attenuation, impedance, and phase shift characteristics as a function of frequency, and tend to produce echoes as described above. Types of loading developed for use on incidental cables occurring in circuits employed for carrier telephone and carrier telegraphy operation[2] were employed to reduce these effects to a minimum. This carrier loading is designed so that when used on No. 13 A. W. G. cable circuits it provides an impedance which approximates very closely that of the open wire. With a spacing of about 930 feet between loading coils, this loading has a nominal cutoff of about 45,000 cycles, which corresponds to an effective transmission range extending up to about 36,000 cycles. In order to obtain a close match between the impedances of the open-wire and the cable pairs, thereby avoiding impedance irregularities, 13-gage pairs were selected for the television circuits in all of the cables.

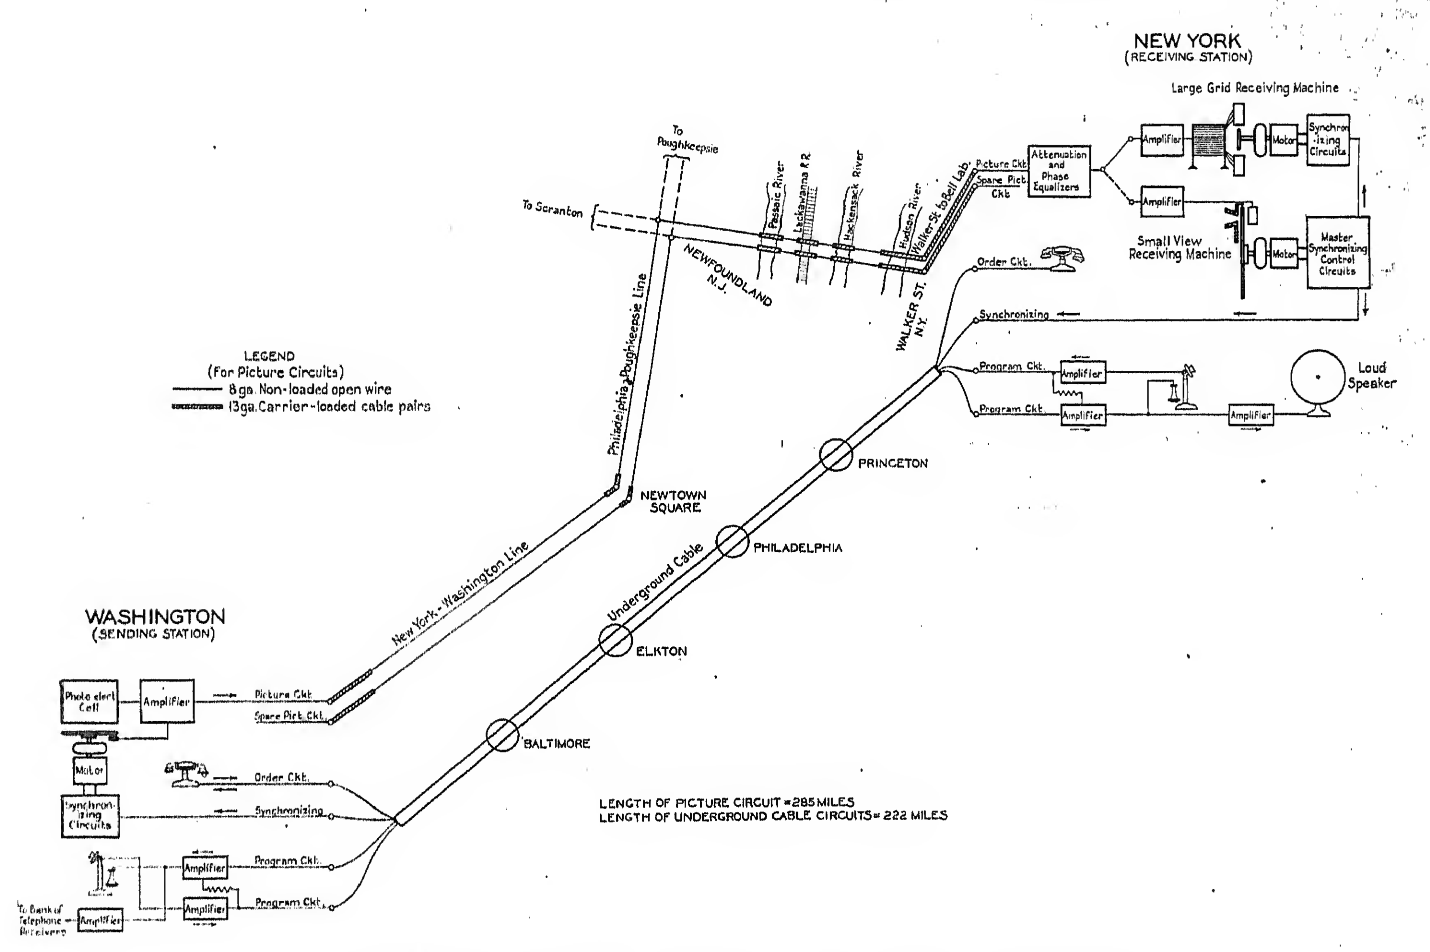


FIG. 2—SCHEMATIC DIAGRAM OF CIRCUITS FOR TELEVISION DEMONSTRATION

The length of the submarine cable under the Hackensack River (about 1100 feet) was too great to permit the use of regular carrier loading, and a special loading arrangement having a slightly lower cutoff was, therefore, designed for this cable.

EQUALIZATION

Requirements. The requirements for the lines were stated earlier. In order to meet these overall requirements it was necessary to apply special forms of distortion-correcting networks.

2. *Development and Application of Loading for Telephone Circuits*, T. Shaw and W. Fondiller, JOURNAL A. I. E. E., Vol. XLV, pages 253-263, March, 1926.

Weather Changes. The above requirements applied, of course, to all of the various weather conditions to which an open-wire circuit is subject. Due to the changes in the leakage conductance occurring at the insulators, the attenuation of an open-wire circuit varies with changing weather conditions. This change is particularly important at the higher frequencies. At 20,000 cycles, for example, the attenuation of a

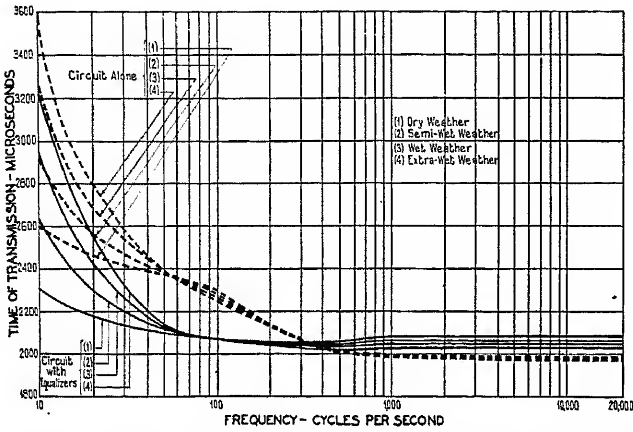

FIG. 3—COMPUTED PHASE DELAY (β/ω) OF TELEVISION CIRCUIT WITH AND WITHOUT EQUALIZERS

165-mil open-wire pair may vary as much as 40 per cent for a change from dry weather to extra wet weather. For the circuit between Washington and New York this represents a possible attenuation change of about 10 T U, or a change of 10 to 1 in the magnitude of the received power. At 1000 cycles, the effect of wet weather is comparatively small, so that the net effect

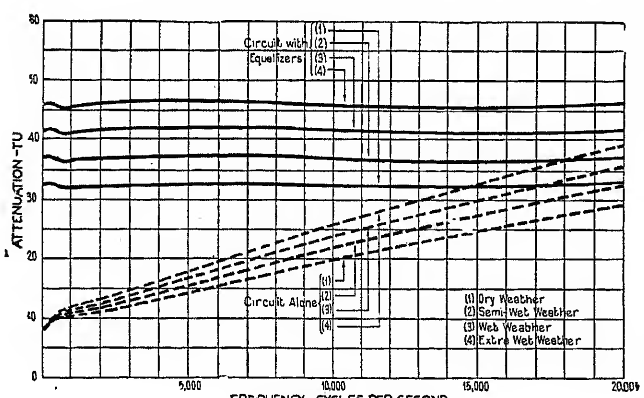

FIG. 4—COMPUTED ATTENUATION CHARACTERISTICS OF TELEVISION CIRCUIT WITH AND WITHOUT EQUALIZERS

of the weather variations is to change the requirements for the attenuation equalizers. The phase shift introduced by an open-wire pair likewise varies to some extent with changes of weather, although the percentage variation is much smaller than in the case of the attenuation. In view of these variations in the line characteristics it was decided to provide basic networks which would equalize for dry weather conditions, and to make available, in addition, several steps of equalization which would compensate for changes in the direction of wet weather.

Low-Frequency Network. Computed curves of attenuation and phase delay for the overall Washington-New York circuit without correcting networks are shown in Figs. 3 and 4, respectively. The form of the dry weather attenuation curve suggested the use of two correcting networks, one for low frequencies, the other for high frequencies. The network which was designed to equalize the attenuation at the lower frequencies is illustrated in Fig. 5. This network, in addition to equalizing the low-frequency attenuation, was made to provide sufficient correction for the low-frequency phase characteristic. It also proved satisfactory for all weather conditions.

High-Frequency Network for Dry Weather. The complete network for the correction at high frequencies

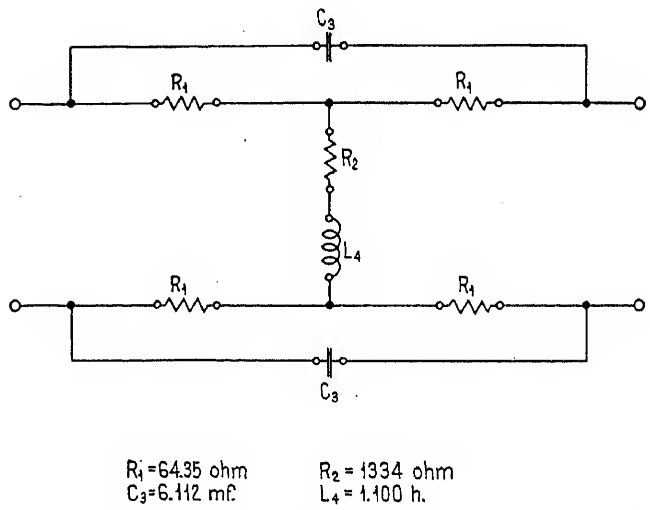

FIG. 5—LOW FREQUENCY EQUALIZING NETWORK (DRY AND WET WEATHER)

under dry weather conditions was designed in two parts, an attenuation equalizer and a phase corrector. These two structures are illustrated in Fig. 6. The computed dry weather attenuation and phase delay resulting with the use of the combined low-frequency and high-frequency networks are illustrated in the curves of Figs. 3 and 4. It will be noted that the corrected attenuation curve is constant to within approximately ± 0.3 T U, while the corrected time of transmission falls well within the prescribed limits.

Weather Change Networks. Correction for the additional distortion introduced by changes from dry to wet weather was provided by three additional networks which were, for convenience, of identical design. The results obtained by using one, two, or three of these networks were made to correspond, respectively, to three assumed weather conditions which may be designated semi-wet, wet, and extra-wet. These three conditions were determined upon the basis of the range

of leakage conditions which exist on open-wire lines under different weather conditions.

The attenuation equalizing and phase correcting networks for one of these steps are illustrated in Fig. 7, while the computed attenuation and time of transmission obtained by the use of the three different steps of weather correction are shown in Figs. 3 and 4.

The networks described above are of the "constant-resistance" type, whose characteristic impedance is a

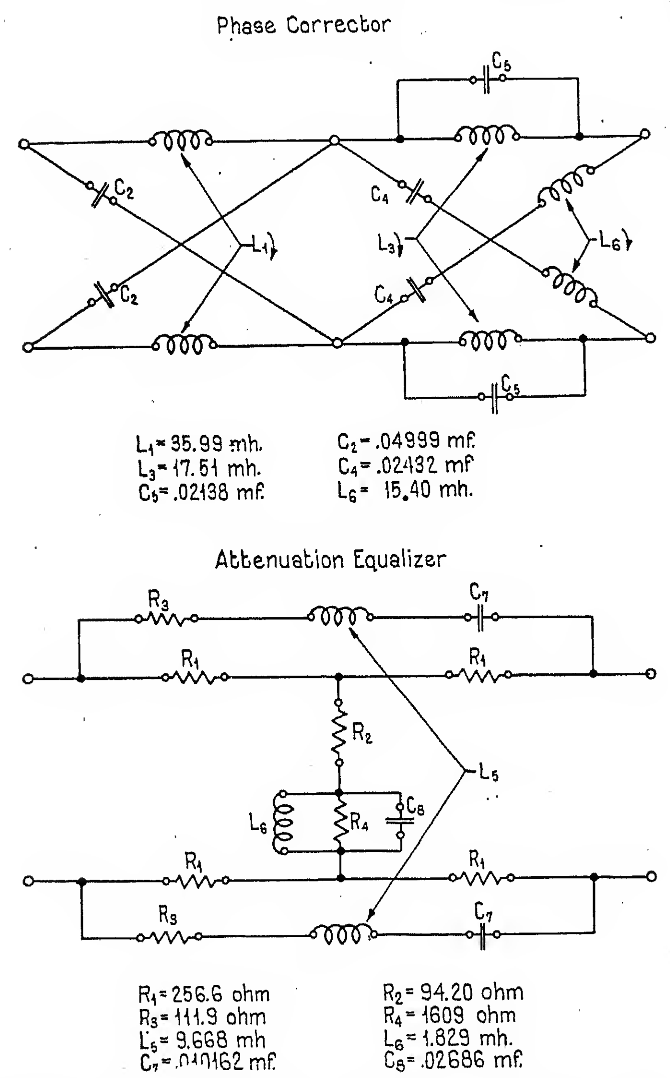

Fig. 6—High Frequency Equalizing Networks (Dry Weather)

pure resistance at all frequencies.[3] These networks are designed to be connected in series. The methods used in the design of the networks involve a large amount of mathematical theory, a discussion of which is not necessary for the purposes of this paper.

Synchronizing and Voice Circuits

So far the discussion has dealt only with the problem of transmitting the television currents. In addition to this, there is required the transmission of voice currents and of synchronizing currents. It is entirely feasible to transmit these currents together with the television currents over a single circuit. However, for the purpose of simplification, separate facilities were employed in the television experiments for picture, voice, and synchronizing currents.

The diagram in Fig. 2 shows the circuits which were actually provided for the demonstrations. It will be seen that in addition to the two picture or television circuits, there were provided a synchronizing circuit, a four-wire "program" circuit, and an order circuit.

The method of synchronizing the sending and the receiving machines has already been described in the paper by Mr. Stoller. It requires two currents, one having a frequency of about 18 cycles and the other

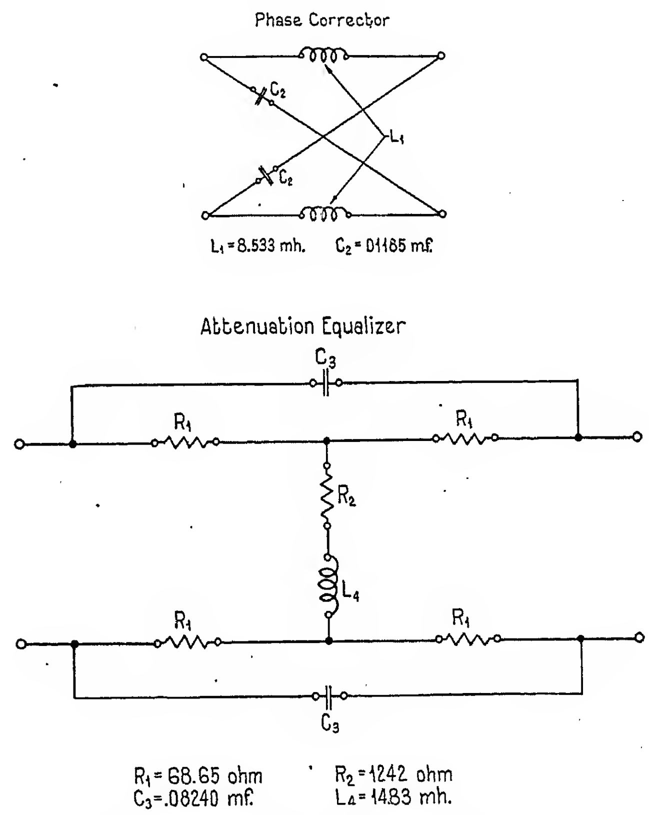

Fig. 7—Weather Change Equalizing Networks

about 2125 cycles. In order that an ordinary telephone circuit might be used for this purpose, the lower frequency was made to modulate by means of a telegraph relay, a carrier current having a frequency of about 750 cycles per second. An amplifier-detector at the receiving end of the synchronizing system demodulated the 750-cycle current, delivering 18 cycles to the television apparatus.

The requirements for the synchronizing circuit were that it must transmit a narrow range near 750 cycles, and the single frequency of 2125 cycles. These synchronizing frequencies are determined by the speed of the motors, which was chosen so that the frequencies would be suitable for transmission over two channels of

3. Partially described in U. S. Patent No. 1,603,305 to O. J. Zobel.

a voice-frequency carrier telegraph system,[4] but later it was found more convenient to use a separate telephone circuit.

The circuits labeled "program" provided telephonic communication between the observer at New York and the person being viewed at Washington. A loud speaker was also connected to this circuit at New York to transmit the voice to the audience when the large grid receiving arrangement was employed. A special by-passing connection was provided between the amplifiers at the terminals of the circuit so that speech from the local microphone could be heard as well as speech from the distant city.

The order circuit was for the purpose of providing communication between the engineers operating the television apparatus.

Line Measurements

In order to determine that the circuits set up as outlined above were satisfactory, their overall characteristics were measured. Certain matters of interest in this work are noted below.

Measurements of Envelope Delay. In order to measure the envelope delay to an accuracy comparable to the requirements for the lines, it was necessary to develop special apparatus. Fig. 8 shows in schematic form the circuits of the apparatus designed for this purpose. The apparatus measures not the absolute envelope delay of a circuit, but the relative delay of one circuit at any frequency from about 600 cycles to 20,000 cycles or more with respect to the delay on the other circuit at a fixed frequency.

The functioning of the apparatus may be briefly described as follows: Simultaneously into each line there was transmitted a carrier current, each carrier being modulated by 250-cycle current from the same oscillator. The modulation was accomplished in push-pull vacuum tube circuits so that the undesired products of modulation were eliminated by balance. The carrier on the line under measurement was adjusted to the frequency at which a measurement was desired, and the carrier on the other circuit, used for reference, was kept at a fixed frequency of 5100 cycles.

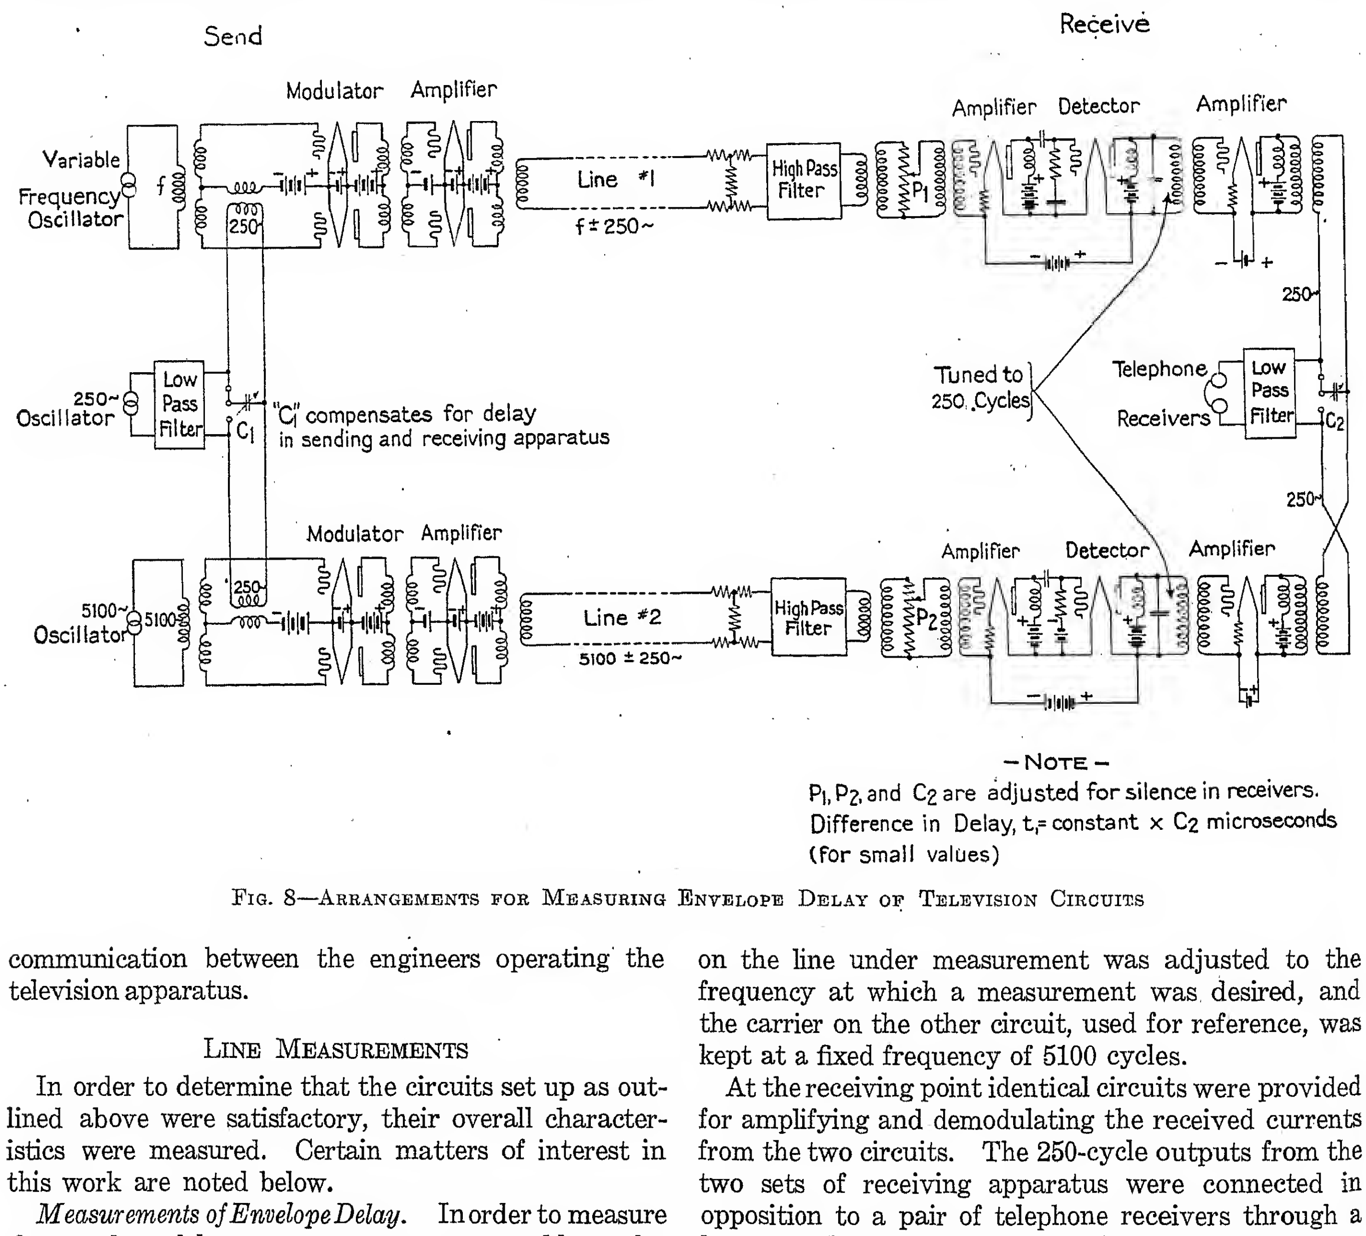

Fig. 8—Arrangements for Measuring Envelope Delay of Television Circuits

At the receiving point identical circuits were provided for amplifying and demodulating the received currents from the two circuits. The 250-cycle outputs from the two sets of receiving apparatus were connected in opposition to a pair of telephone receivers through a low-pass filter. Potentiometers P_1 and P_2 were provided for adjusting the relative intensities of the two 250-cycle output voltages and a condenser C_2 was arranged so that it could be used to change the phase of e ther of the 250-cycle voltages. It is evident, then,

4. *Voice-Frequency Carrier Telegraph System for Cables*, B. P. Hamilton, H. Nyquist, M. B. Long, and W. A. Phelps, Journal A. I. E. E., Vol. XLIV, pages 213-218, March, 1925.

that by making suitable adjustments the two voltages could be adjusted to exactly the same intensity and opposite phase so that no sound is heard in the telephone receivers. As long as the value of C_2 is small, the envelope delay of one line at the carrier frequency with respect to the delay of the other line at 5100 cycles is proportional to the value of C_2.

The condenser C_1 shown at the sending station is for the purpose of introducing a phase shift in the 250-cycle current of either channel relative to the other in order to compensate for the differences in delay of the apparatus itself at the two frequencies. The value of C_1 was determined by experiment before moving the sending apparatus to Washington and was adjusted to its calibrated value for each frequency when the oscillator frequency was adjusted.

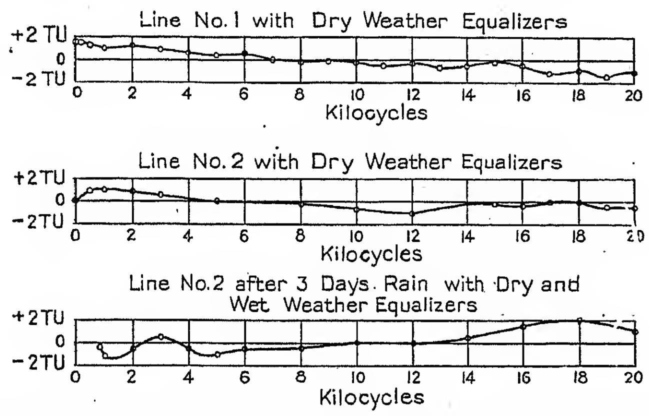

Fig. 9—Measured Attenuation Characteristics of Line Circuits Plus Equalizers

The measurement of the phase shift of the 250-cycle current, which is transmitted by means of a carrier over a circuit as described above, is actually a measurement of the difference between the phases of the two received side-band currents situated 250 cycles either side of the carrier. The envelope delay is equal to $\frac{\Delta \beta}{\Delta \omega}$ where $\Delta \omega$ equals 2π times 500, and $\Delta \beta$ equals the measured difference in phase of the two side bands in radians.

Measurements and Performance. How well the requirements which were set up earlier were met by the lines and the distortion-correcting networks is shown in Figs. 9 and 10. The attenuation characteristics are well within the established limits, and the phase characteristics show only a single slight departure for one circuit in a very narrow range of frequency. It is of interest, in view of the fact that the distortion-correcting networks were designed and built before any measurements were made on the lines they were to fit, that no changes or adjustments were found to be necessary in the networks, in order to obtain these characteristics.

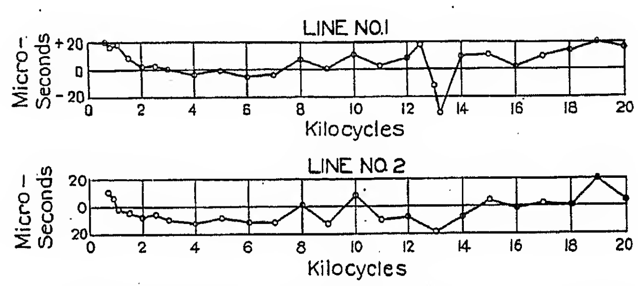

Fig. 10—Measured Envelope Delay of Line Circuits Plus Equalizers

Comparison of the television images obtained from transmission over the line with those obtained from transmission from one side of the room to the other, showed that no difference in quality could be observed.

Radio Transmission System for Television

BY EDWARD L. NELSON*
Member, A. I. E. E.

Synopsis.—*Starting from the general requirements imposed on the transmitting medium, this paper discusses the engineering of a radio system for television purposes and describes the radio facilities actually employed for the recent Bell System demonstration. The tests to which the system was submitted to determine its suitability are outlined and the measured frequency-response characteristics are shown. An interesting phenomena due to multi-path transmission, the production of positive and negative secondary images, is reported. A brief series of experiments concerned with the transmission of both voice and image "on a single wavelength" is also described.*

* * * * *

IN other papers of this symposium, the general nature of the television problem has been discussed, the scope of the recent Bell System demonstration has been outlined, terminal apparatus for television has been described, and the general requirements to be met by the transmitting agency have been formulated. This paper is concerned with the problem of engineering a suitable radio system for television purposes and with a description of the radio facilities actually employed for the demonstration.

Requirements Imposed on the Radio System

The radio experiments were conducted from the Bell Telephone Laboratories' Experimental Station 3XN at Whippany, New Jersey. Between this point and the main laboratories' building at 463 West Street, New York City, some 22 miles distant, three separate communication channels were required—one for the picture, a second for synchronizing, and a third for speech and music. The demonstration being of a three-cornered nature involving New York, Washington, and Whippany, it was deemed to be highly advantageous to transmit the necessary synchronising currents for both the wire and radio systems from a master generating set located in the auditorium of the West Street building. Hence the synchronizing channel was required to operate from New York to Whippany, while the picture and speech channels necessarily transmitted in the reverse direction.

From the radio standpoint, the problem presented for solution may be described as follows:

1. There is given television transmitting and receiving apparatus designed to work into and out of specified impedances at stated signal energy levels. Signal components ranging in frequency from 10 to 20,000 cycles must be transmitted with as little discrimination with respect to either amplitude or phase as reasonable design practises will permit. It is required that a suitable radio system be designed to afford satisfactory transmission between terminals when operated under prevailing conditions with respect to static, other radio traffic, and local electrical disturbances. The maximum allowable "noise" level is probably somewhat arbitrary but it has been found that if the ratio of signal to interference current is 10:1 the results are satisfactory. The variation of amplitude with frequency should probably not exceed $\pm$ 2 T U[1] at any point in the required signal band. The equivalent of the circuit must be substantially constant; in other words, no fading effects can be tolerated. In this respect a variation of perhaps 3 T U is the maximum allowable.[1]

2. For synchronizing purposes, a second channel must be provided to transmit 17.7 and 2125 cycles, the impedances and the signal energy levels at both ends of the circuit being known. The grade of transmission required in this case is probably considerably lower than that needed for the picture circuit but stable operation must be assured.

3. Arrangements must also be made for a high quality telephone channel to transmit speech and music for loud speaker reproduction.

4. All of these channels must, of course, be capable of operating simultaneously without mutual interference and without effect on established radio services.

Preliminary Survey

In the vicinity of New York, an assignment of this type is surrounded with unusual difficulty due to the serious congestion which exists in the ether. Operations were started, therefore, by undertaking a survey of available frequency bands at periods of the day during which transmission might be required.

The pioneering nature of the project and the character of the apparatus available led to an early decision to base the system on the transmission of the carrier and both sidebands. Since the upper limit for the signal was specified as 20,000 cycles, an interference free band somewhat greater than 40,000 cycles in width was, therefore, required. The unusual width of this band indicated the desirability of fixing upon a relatively high carrier frequency. No readily available substitute for the ordinary type of tuned circuit was at hand and such circuits discriminate seriously against side frequencies differing by more than a few per cent from the frequency to which they are adjusted.

The results of the survey disclosed two bands somewhat wider than that required centering approxi-

1. Definitely agreed on limits were essential to proper co-ordination of the various development activities and figures of the order mentioned were assumed for design purposes.

mately about 1575 and 1750 kilocycles. It was also conclusively demonstrated that the operation of the synchronizing channel at a frequency above the broadcasting band was entirely out of the question. With two broadcasting stations located in the immediate neighborhood, one producing a field strength of perhaps 50 millivolts per meter and the other several volts per meter, the operation of a third transmitter on an adjoining frequency with the maximum obtainable separation between antennae, resulted in an almost continuous interference spectrum. It was decided, therefore, to transfer the synchronizing channel to a frequency of the order of 185 kilocycles, which would be sufficiently remote to remove interference from this source, and to make further studies in the regions about 1575 and 1750 kilocycles based on transmission from Whippany. No difficulty was anticipated in making suitable arrangements for the speech channel on account of the narrower band required and the well-known nature of the problem.

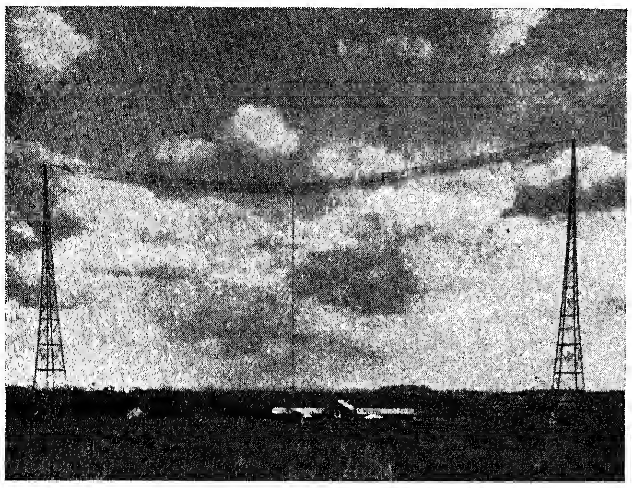

FIG. 1—GENERAL VIEW OF THE WHIPPANY STATION, 3 X N

THE WHIPPANY STATION, 3XN

A general view of the station site at Whippany is shown in Fig. 1. The property consists of some 47 acres. The main laboratory building, which is located near its center, is a two-story structure affording approximately 18,000 square feet of floor space. The principal antenna system involves two 250-foot steel towers with a suitable buried ground system, which is placed some 500 feet out in front of the building in order that the latter may be clear of the denser portion of the electric field. This antenna was assigned to the picture channel. For the voice channel, a separate structure located 500 feet in the rear of the laboratory building or approximately 1000 feet from the other was employed. The original supports in this second case were 60-foot wooden masts but subsequently metal topmasts were added, bringing the total height to 100 ft. Both antennae were energized by means of radio-frequency transmission lines. The antenna tuning and coupling apparatus was housed in small buildings placed under the center of each antenna, that for the larger structure having a copper roof which was securely connected to the ground network.

This type of installation is thought to afford a number of advantages. By separating the building and the antenna it becomes a much simpler matter to control the electrical factors which enter into the design of the latter. Removing the building from the field tends toward reduced dielectric and eddy current losses and consequently toward higher antenna efficiency. The resulting improvement may be expected to more than compensate for the slight loss in the line, which should not exceed 3 per cent. Removing the field from the building is equally advantageous in that it simplifies the precautions which normally have to be taken to prevent the radio-frequency energy from affecting the performance of audio amplifiers and other supplementary vacuum tube apparatus. The most serious disadvantages arise from the fact that the antenna must be tuned and the current in it measured at a point remote from the transmitting apparatus proper.

In spite of the fact that the station building was not directly under either antenna, some difficulty was anticipated from radio-frequency fields produced within the transmitting equipment due to the relatively high amplification employed with the photoelectric cells. In order to minimize trouble of this nature a special shielded studio was constructed in one of the wings of the building to house the television terminal apparatus. Walls, ceiling, and floor were completely covered with No. 24 gage sheet copper lapped about one inch and carefully soldered. The windows were covered with fine copper gauze. The door was covered with sheet copper which was carried around the edges so that in closing it made a firm wiping contact with the surrounding frame. Circuits for lighting and miscellaneous power service were led in through two specially constructed transformers fitted with grounded copper shields between the primary and secondary windings.

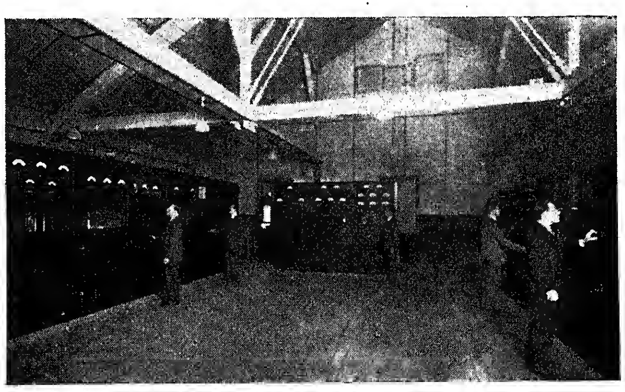

FIG. 2—OPERATING ROOM AT 3 X N. TRANSMITTER FOR TELEVISION CHANNEL ON THE RIGHT. POWER SUPPLY UNIT AND RADIO TRANSMITTER FOR THE SPEECH CHANNEL IN THE CENTER AND ON THE LEFT, RESPECTIVELY

The picture circuits leading to the radio transmitter, the microphone circuits, and the necessary studio signal and control circuits were run in lead cable and in most cases were brought into the room through suitable radio-frequency filters enclosed in metal boxes attached to the copper sheathing. In order to avoid the possibility of the heavy current leads to the arc bringing in radio-frequency energy, and to eliminate the noise and heat from the arc, provision was made for mounting the latter in its metal cabinet outside of the room. The circular opening through which the light beam was projected into the room was protected by the lamp cabinet which was also grounded to the sheathing. Satisfactory acoustic conditions within the studio were obtained by applying celotex wall board over the copper and by the use of suitable floor coverings.

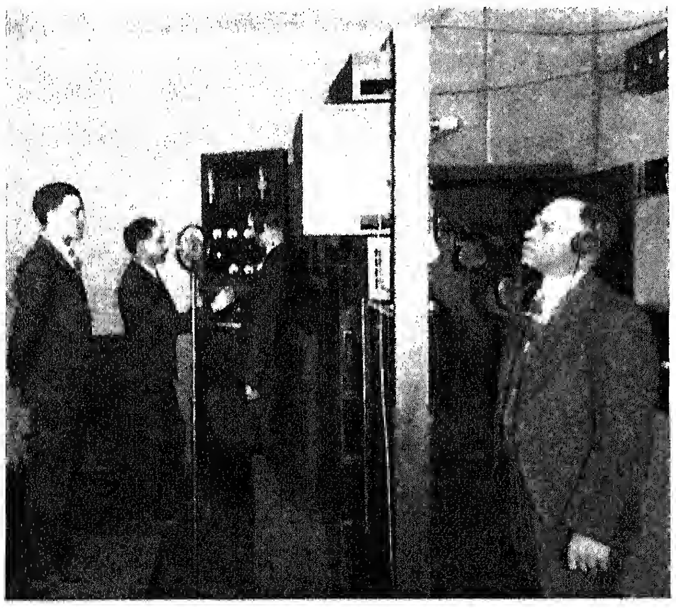

FIG. 3—TELEVISION TRANSMITTING APPARATUS IN THE STUDIO AT WHIPPANY

TRANSMITTING AND RECEIVING APPARATUS

For the television channel, arrangements were made to install a standard Western Electric 5-B Radio Broadcasting Transmitter and to modify it for the purpose. This transmitter is a 5 kilowatt unit (carrier output without modulation) designed for high quality telephone transmission in the 500-1500 kilocycle band. It will transmit signal components ranging from 50 to 5000 cycles without noteworthy discrimination. At 30 cycles and at 10,000 cycles there is some loss in efficiency and beyond these points the characteristic curve falls rapidly. The necessary changes, therefore, involved both the radio and audio circuits, the latter phase of the problem being perhaps the more difficult.

The schematic circuit of the modified transmitter is shown in Fig. 4. The revised radio frequency circuits were very similar to the standard arrangement, the changes mainly affecting the magnitudes of various coils and condensers. The output circuits were, of course, redesigned to meet the conditions imposed by the transmission line. The circuit was of the master oscillator-modulating amplifier-power amplifier type. The master oscillator employed a 50-watt tube operating in a circuit designed to afford a high degree of stability. This was connected to the input of the modulating amplifier through two radio-frequency stages, also employing 50-watt tubes. These two stages precluded the possibility of the oscillator frequency being appreciably altered by effects due to modulation. The modulating amplifier employed two 250-watt tubes in parallel and operated on the Heising system. In the standard equipment, the audio stages involve one 50-watt tube and two 250-watt tubes in parallel. To meet the more rigorous requirements of television with an ample factor of safety, this portion of the transmitter was removed from service and a specially constructed three-stage amplifier was substituted. As shown in the drawing, the latter consisted of two 50-watt resistance-coupled stages and a final power stage based on a 5-kilowatt water-cooled tube which raised the signal currents to a power level of approximately one-half kilowatt.

In order that it might be possible to check the performance of the radio transmitter under all operating conditions, a suitable monitoring rectifier was constructed and coupled to the output circuit of the radio-frequency power amplifier. A circuit was run back to suitable switches on the television control panel so that either the output of the photoelectric cell amplifiers or the rectified output of the radio transmitter could be impressed on the pilot lamp of the television transmitter. By comparing the two images, it thus became a relatively simple matter to detect any serious maladjustment in the radio apparatus.

The problem of providing a suitable transmitter for the speech channel was rendered quite simple by the fact that at the time there was in process of development at Whippany a 50-kilowatt equipment intended for broadcasting applications. The detailed description of this transmitter is beyond the scope of the present paper. It may be said, however, that it consists of a piezo-electrically controlled master oscillator employing a 50-watt tube directly followed by a 50-watt modulating amplifier. Modulation is by the Heising system, employing one 50-watt and one 250-watt tube in the audio stages. The output of the modulating amplifier is amplified by three push-pull, neutralized, radio-frequency stages the last of which employs six water-cooled tubes at approximately 17,000 volts. This set is capable of delivering 50 kilowatts (unmodulated carrier) to the antenna and during modulation instantaneous peaks approaching 200 kilowatts are attained.

The radio receiver employed at Whippany for the reception of the synchronizing signals at 185 kilocycles presents no features of unusual interest. A double-tuned input circuit was used followed by three stages

of radio-frequency amplification, a detector, and two audio stages of conventional design employing transformer coupling. No serious difficulty was encountered in obtaining ample selectivity to insure satisfactory operation in the face of the strong local signals but care was necessary in locating the receiver and in laying out the antenna in order to avoid the inductive type of interference which is almost always experienced in the immediate vicinity of a large radio station. The receiving antenna was located approximately 700 feet from the two transmitting radiating systems.

The receiver employed at the New York terminus of the television channel presented a somewhat knotty problem on account of the relatively wide frequency band which it was required to pass while providing the maximum discrimination against interference. The width of the required band pointed very definitely toward the superheterodyne. This type of circuit is also very stable, permits of all the amplification that may be needed or that may be employed under ordinary noise conditions, and is very selective against interference immediately adjacent to the desired band. It is quite susceptible, however, to interference from components differing from the desired carrier frequency by an amount approximately equal to the intermediate frequency. If the interfering component lies in the neighborhood of the frequency of the oscillator, beats will be produced which may or may not pass the intermediate-frequency amplifier and the associated filters depending on their design. If the interfering component lies on the opposite side of the wanted carrier from the oscillator and differs from the former by the intermediate-frequency, it will be passed by the receiver, subject only to the attenuation due to the radio-frequency circuits (the input circuits tuned to the wanted carrier). This characteristic must be given careful consideration in the design of selective receivers of the superheterodyne type and has led to the introduction of carefully designed, loosely coupled, input circuits or an initial tuned radio-frequency stage for this purpose. Neither of these expedients were possibilities in the television receiver, however, because of the extraordinary width of the required transmission band. Recourse was had, therefore, to a triple detection arrangement. Speaking somewhat in the vernacular, the desired signal was "beat up" to 5000 kilocycles where it was passed through sharply tuned coupled circuits, then "beat down" to 120 kilocycles, amplified, filtered, and rectified, finally passing through a suitable low pass filter, audio amplifier, and output transformer to the television reproducing apparatus.

The circuit arrangement is shown schematically in Fig. 6. Two tuned circuits with capacity coupling were connected to the input of the first detector or

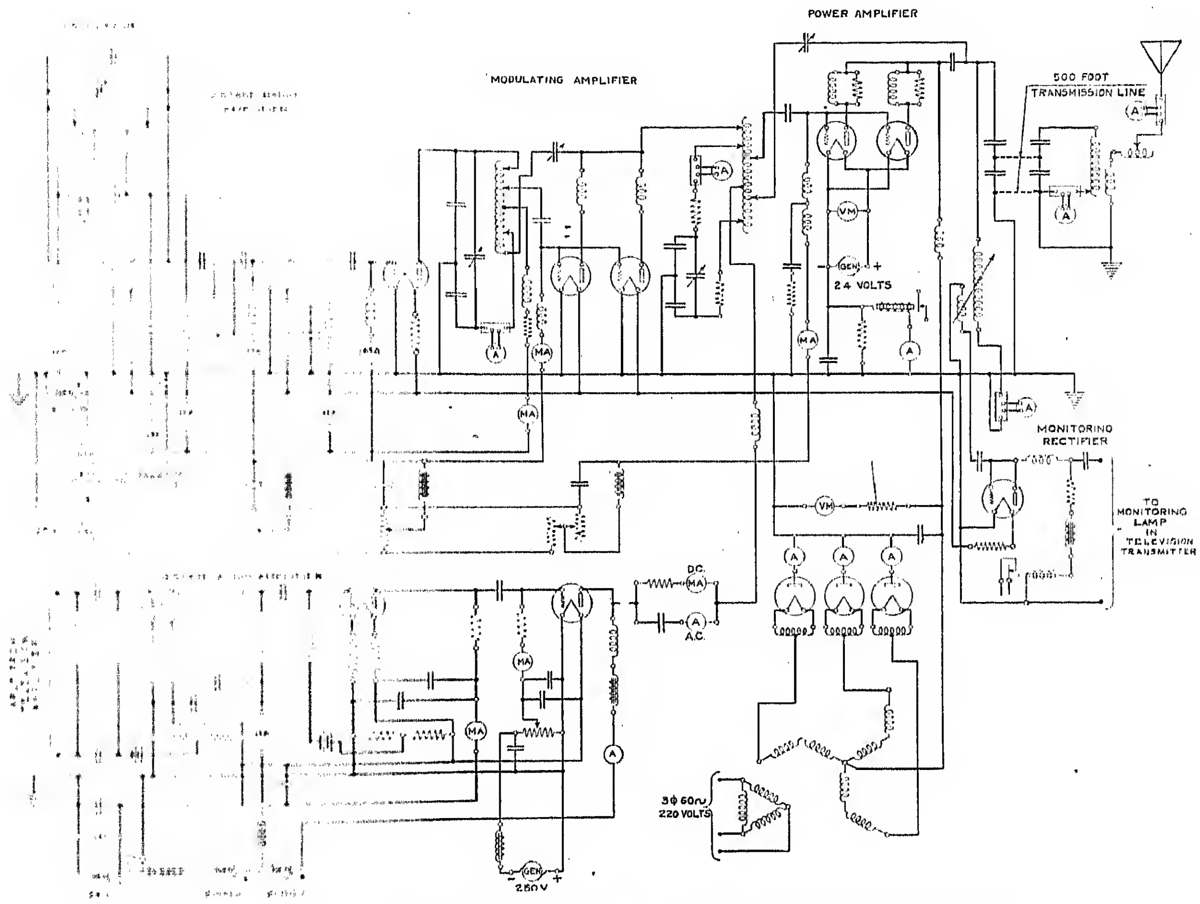

Fig. 1 Schematic of Radio Transmitter for Television Channel

modulator. A relatively tight coupling was employed to produce the well-known double-peaked resonance curve capable of affording the required band width. The antenna was not tuned but was loosely coupled to the selective circuits by means of an adjustable capacity. The incoming radio signal was impressed upon the grid

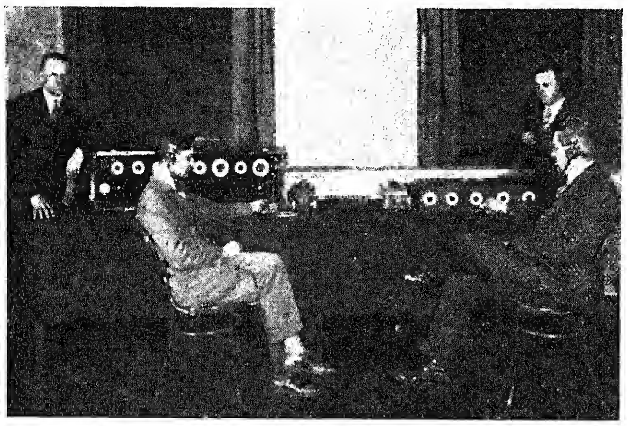

Fig. 5—Radio Receiving Equipment for the Television and Speech Channels in the Auditorium of Bell Telephone Laboratories, New York

of the modulator tube along with a suitable voltage from an oscillator operating at 6575 kilocycles. The 5000 kilocycle components which resulted were selected by means of two carefully designed tuned circuits also capacity coupled. The purpose of this stage in the process will be evident if it is appreciated that at 1575 kilocycles ± 20 kilocycles requires a 2.6 per cent band while at 5000 kilocycles the same side frequencies require only a 0.8 per cent band. In the latter case, therefore, it is possible to employ materially sharper circuits without discriminating against the higher signal components. The 5000-kilocycle circuits connected to the grid of a second detector or modulator tube upon which suitable voltages from a 5120 kilocycle oscillator were impressed. The 120-kilocycle components in the output of this modulator were selected by means of a band-pass filter which worked into a two-stage intermediate-frequency amplifier. A second band-pass filter led to the third or final detector. A 20-kilocycle low-pass filter was employed in the plate circuit of the latter. This filter was designed for a low input impedance at 120-kilocycles in order to meet the necessary condition for efficient rectifier action and it also served as a coupling element for the audio stage which followed. A special output transformer with a permalloy core was provided to step down to the relatively low impedance of the line leading to the television apparatus proper.

A superheterodyne receiver of more conventional design was employed for the speech receiver. The circuit arrangement involved a double-tuned input circuit, one tuned radio-frequency stage, oscillator and modulator, two intermediate-frequency stages, detector and one audio stage. It was highly selective and afforded substantially distortionless transmission for signal frequencies ranging from 50 to 5500 cycles.

The transmitting equipment for the synchronizing channel consisted of a Western Electric 6-A Radio Broadcasting Transmitter modified to operate at 185 kilocycles. In order to avoid the necessity of transmitting directly the 17.7-cycle component required for synchronizing purposes, a 760-cycle carrier was modulated at 17.7 cycles by means of a relay and impressed upon the input of the radio transmitter together with the steady 2125-cycle component. At the receiving end, the 2125 and modulated 760-cycle components were separated by means of suitable filters, and the latter rectified to produce the desired 17.7-cycle current.

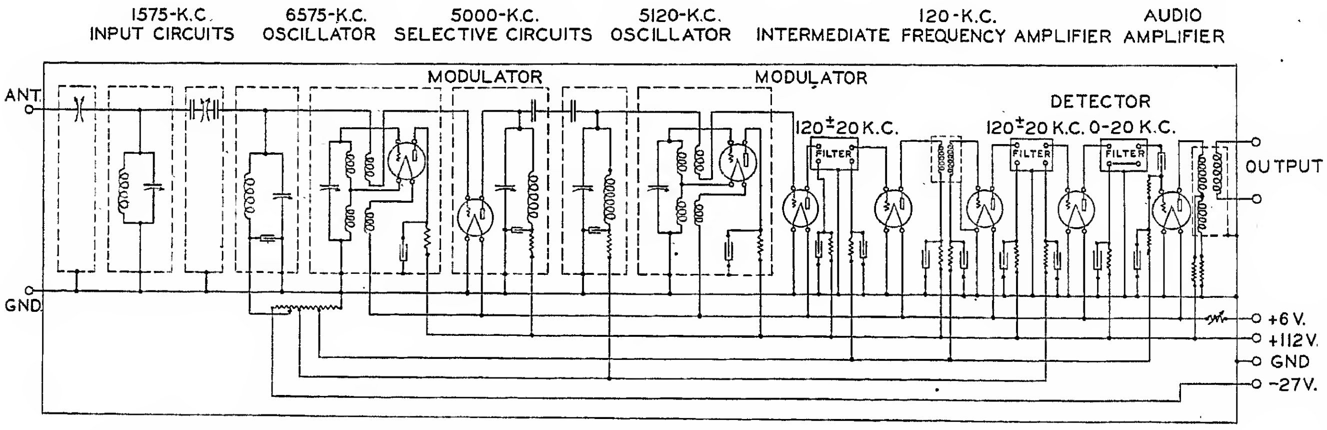

Fig. 6—Schematic of Triple Detection Receiver for Television Channel

Tests of the System

As soon as the various apparatus units could be made ready for service, a comprehensive series of transmission tests was undertaken. In order to determine the relative suitability of the 1575- and 1750-kilocycle bands disclosed by the preliminary survey, transmissions from Whippany at intervals throughout the day were arranged. Field strength measurements were taken at the receiving point employing apparatus of the type described by Messrs. Englund and Friis

at the Spring Convention[2] and observations on the relative strength of the received signals were made by inserting a sensitive microammeter in the plate circuit of the third detector of the television receiver. These data indicated that the lower frequency band suffered considerably less attenuation and also afforded much more stable transmission. In spite of the comparatively short distance (approximately 22 miles) marked fading was experienced beginning with the sunset period and increasing in amplitude as the night advanced. The high frequency band proved to be particularly disadvantageous in this respect. It was decided, therefore, to fix upon the lower frequency band and to confine the demonstration to the afternoon when reasonably stable transmission conditions prevailed.

Following the choice of a definite operating frequency, a number of modifications was made in the transmitting antenna to improve its efficiency and increase the field strength at the receiver. This work finally resulted in a measured field strength of approximately 2500 microvolts per meter for an antenna input of 5 kilowatts.

Further consideration of the available data on transmission and traffic conditions and the performance characteristics of the apparatus units involved lead to a choice of 1450 kilocycles for the speech channel. In spite of an antenna input of approximately 30 kilowatts, the initial tests at this frequency were very unsatisfactory due to inadequate field strength at the receiver which necessarily resulted in an abnormally high noise level. The height of the antenna was, therefore, increased from 60 to 100 feet by installing iron pipe topmasts. This change brought the field strength at the receiver to approximately the same value as that obtained for the television channel (2500 microvolts per meter) which was considered to be satisfactory for the purpose.

In order to insure that the reproduction of the picture might not suffer from serious discrimination against essential frequencies at some point in the radio system, very careful tests were made on the individual units and on the system as a whole.

The frequency characteristic of the transmitter was determined by connecting a vacuum tube oscillator producing a relatively pure wave to its input terminals through a suitable network involving a thermal milliammeter and an adjustable artificial line. A rectifier of known characteristics and a second thermal meter protected against radio-frequency currents by means of a low-pass filter were coupled to the output circuit of the water-cooled tubes. Employing a frequency of 1000 cycles, the input was adjusted to produce normal modulation and the readings of the input and output meters noted. The oscillator frequency was then changed by a convenient amount while holding the input reading constant and the artificial line readjusted, if necessary, to produce constant output current. Under these conditions, any change in the setting of the artificial line indicates an equal variation in the transmission efficiency of the transmitter which is evaluated by this method directly in Transmission Units (T U).

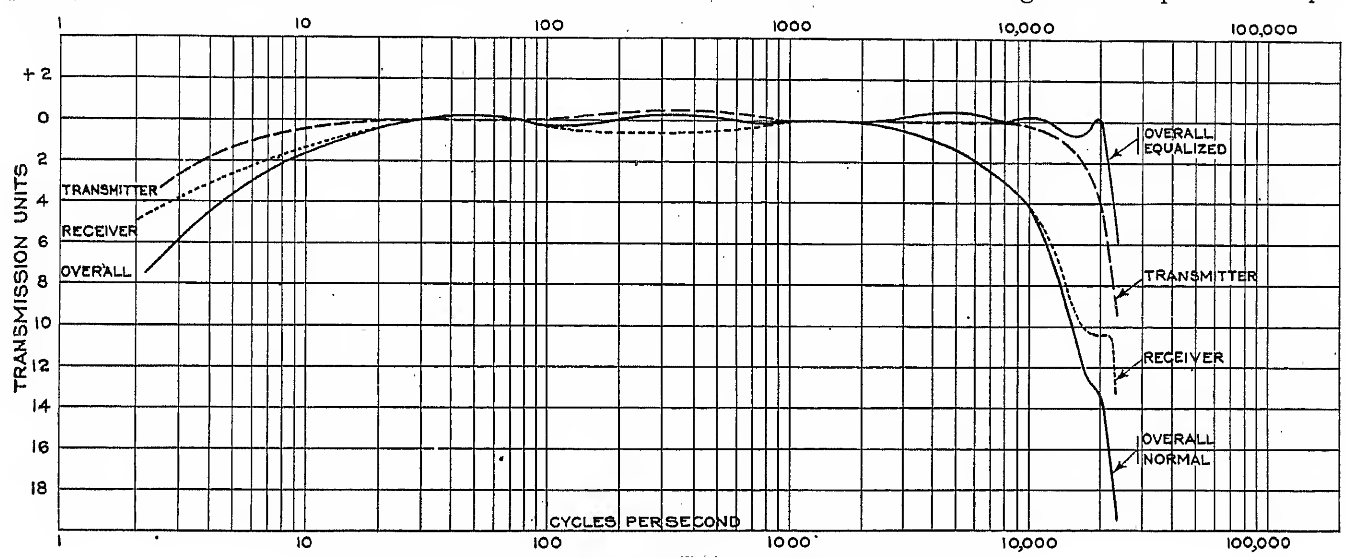

Fig. 7—Measured Characteristics of Television Channel

The characteristic of the receiver was determined in a similar manner. A low power transmitter of known characteristics was connected to it through a suitable attenuating network which, in so far as the receiver was concerned simulated the receiving antenna. The radio-frequency input to the receiver was adjusted to approximately the normal value and a series of measurements taken with variable audio-frequency inputs as indicated above.

The overall measurements were also based on a similar procedure impressing a constant input on the 600-ohm input terminals of the transmitter through a suitable artificial line and adjusting the latter to

2. Methods for Measurements of Radio Field Strengths. C. R. Englund and H. T. Friis. See p. 492.

give a constant current into a 600-ohm load at the output of the receiver, taking necessary precautions, of course, to preclude overloading at any point in the system.

The experimental characteristic curves thus obtained are shown in Fig. 7, where the abscissae represent cycles per second and the ordinates departure from the 1000-cycle value in T U. As will be noted, at the lower frequencies exceptionally good performance was obtained, the overall characteristic being only 2 T U down (or deficient) at 10 cycles and only 6 T U down at 3 cycles. The results for the higher frequencies, however, were not so satisfactory, a loss of approximately 13 T U being observed at 20,000 cycles probably due to the tuned circuits in the receiver. Since modification of these circuits to obtain a flatter characteristic would have been difficult and would have occasioned a noteworthy sacrifice in selectivity, a compensation network was designed for use in the 600 ohm output circuit of the receiver which introduced a negligible loss at 20,000 cycles, a substantially constant loss of 13 T U at frequencies below 2000 cycles, and for intermediate frequencies losses represented by the height of the "normal overall" curve above the horizontal line representing – 13 T U. With this network connected between the receiver and the television equipment, the average level throughout the band was, therefore, reduced some 13 T U but the resulting characteristic as measured beyond the network was that which has been designated "overall equalized." Above 20,000 cycles the characteristics all fell very rapidly which is an indication of the degree of selectivity attained. This was contributed to by the radio-frequency tuned circuits, the band-pass filters in the intermediate-frequency amplifier, and the 20,000-cycle low-pass filter between the final detector and audio amplifier. The individual characteristics of the various filters were designed to be 60 T U down 20 kilocycles from the specified cut-off frequency.

Similar measurements were made upon the speech channel but a less thorough study was deemed sufficient in that case due to the existing background of experience.

Effects of Fading

With the system as outlined above, very satisfactory performance was obtained during the afternoon and early evening hours when reasonably stable transmission conditions were prevalent. Later at night, however, when marked fading became evident, some rather unexpected but easily explainable phenomena were observed which may be of sufficient interest to warrant brief mention.

When marked fading occurred, the normally clear reproduction was accompanied by "ghosts" or additional images which faded in and out in an erratic manner, sometimes appearing as positives and sometimes as negatives. The effect was most clearly observed when using one of the various types of test screens employed, a white card bearing a black diamond-shaped outline, approximately a square with its diagonals vertical and horizontal. With this simple type of pattern, it became evident that the secondary images were additional reproductions which were "out of frame" by a greater or less amount. In other words, each of these additional images consisted of a portion of two diamonds placed side by side with the corners just touching. Images "out of frame" along the vertical axis are frequently seen on the motion picture screen.

The explanation is fairly obvious. The present more or less generally accepted view of fading is that it is a manifestation of transmission along two or more

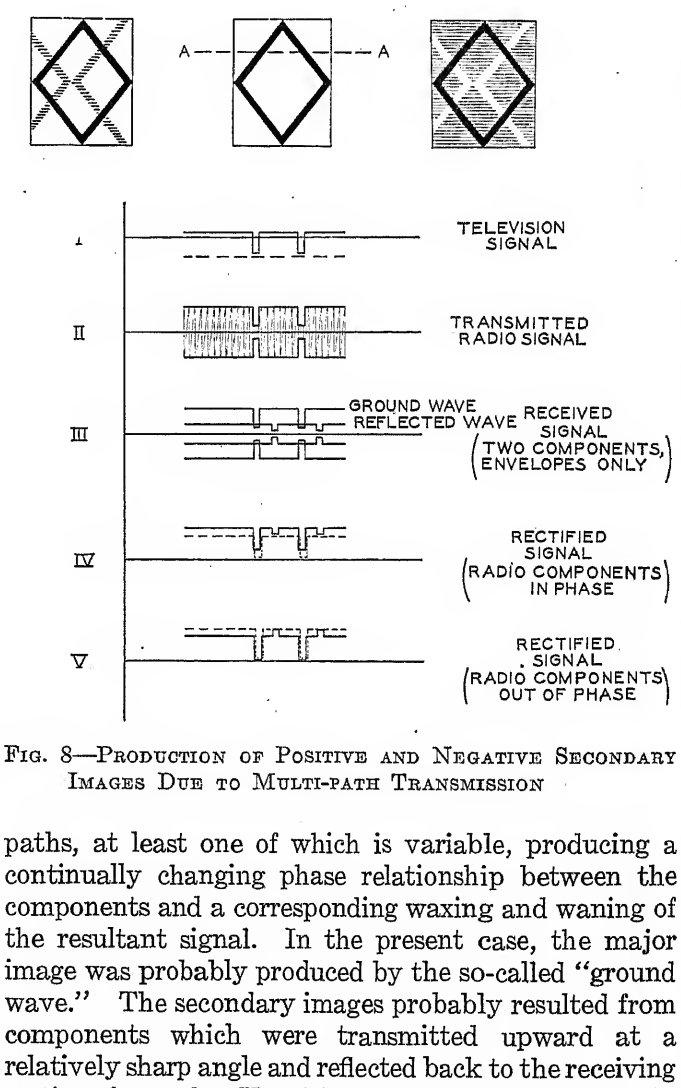

Fig. 8—Production of Positive and Negative Secondary Images Due to Multi-path Transmission

paths, at least one of which is variable, producing a continually changing phase relationship between the components and a corresponding waxing and waning of the resultant signal. In the present case, the major image was probably produced by the so-called "ground wave." The secondary images probably resulted from components which were transmitted upward at a relatively sharp angle and reflected back to the receiving station from the Heaviside layer, the difference in framing being due to the longer time of transmission.

The production of negative secondary images is a most interesting phase of the phenomena. This effect may be explained quite easily by means of a series of signal diagrams such as is shown in Fig. 8. If attention is confined to the interval during which scanning takes place along the line AA, it is evident that the television signal will have the form shown. Amplitudes above the dotted line indicate the current through

the photoelectric cell. Since transformer-coupled amplifiers are employed in the television apparatus, however, the direct component is eliminated and the zero axis for the input to the radio transmitter is the solid line. Sketch II shows the modulated output of the radio transmitter. The received signal, shown in III, is assumed to consist of two components, the larger due to the "ground wave," and the smaller due to reflected energy from the Heaviside layer. The latter lags somewhat because of the greater length of the transmission path. The resultant of these two components will necessarily depend on the relative phase of the two carriers at the receiving point. Two cases are considered: when the components are exactly in phase, and when they are exactly out of phase. The effect at intermediate positions may be readily evaluated from these examples. With the components in phase, the detector output is proportional to their sum which is shown in IV. It is evident that this will result in a major image and a secondary positive image. If the components are out of phase, the rectified signal shown in V results. It is simply a matter of subtracting amplitudes. This resultant consists of the desired signal with the amplitude somewhat reduced which will produce a gray background. The secondary image will be formed by the two small peaks shown and will be lighter than the background, in other words a negative.

A pattern frequently observed was the diamond with a cross through its center due to a secondary image. This represents a change in framing of approximately one half line. With 17.7 pictures per second and 50 lines per picture, this corresponds to a difference in transmission time of $1/17.7 \times 1/50 \times 1/2$ or 5.65×10^{-4} seconds. A rough computation of the height of the reflecting layer based on this figure and a distance of 22 miles between transmitting and receiving stations gives 100 kilometers, which is substantially in agreement with determinations made by other methods.

Transmission of Voice and Image with a Common Carrier Frequency

Following the demonstration, a brief series of supplementary tests was arranged to obtain some appreciation on experimental grounds of the problems involved in transmitting both voice and image with a single radio transmitter. The system employed may be considered as the extension of carrier current technique to radio, but has been described in various other terms: "multiplex radio," "double modulation," "the Hammond system," etc. The output of a 30,000 cycle oscillator was modulated with the speech signal. The resulting carrier and sidebands were selected by means of a suitable filter passing frequency components ranging between 25,000 and 35,000 cycles and impressed on the input terminals of the radio transmitter along with the 10 to 20,000 cycle signal from the television apparatus. A suitable low-pass filter was employed in the line to the latter in order to preclude "crosstalk" due to 25,000-35,000 cycle energy working back into the final amplifier stages. The input to the radio transmitter thus consisted of a band extending from 10 to 20,000 cycles together with a 25,000 to 35,000 band, with a particularly strong component at 30,000 cycles representing the low-frequency carrier.

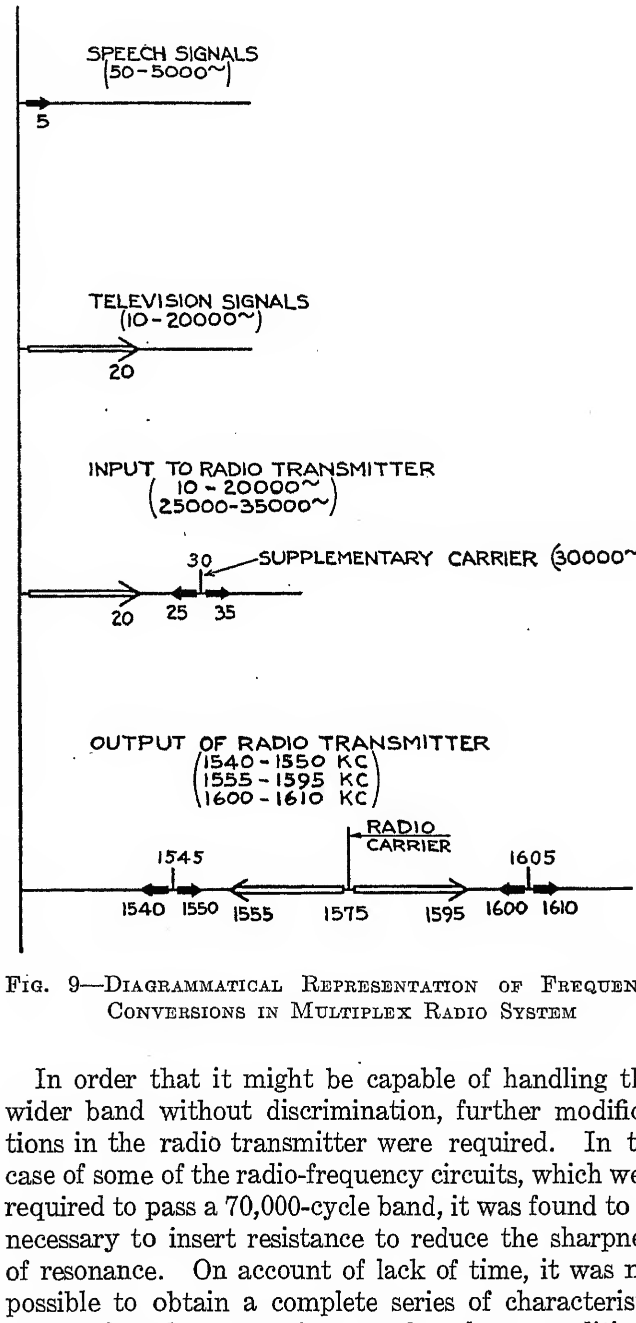

Fig. 9—Diagrammatical Representation of Frequency Conversions in Multiplex Radio System

In order that it might be capable of handling this wider band without discrimination, further modifications in the radio transmitter were required. In the case of some of the radio-frequency circuits, which were required to pass a 70,000-cycle band, it was found to be necessary to insert resistance to reduce the sharpness of resonance. On account of lack of time, it was not possible to obtain a complete series of characteristic curves for the transmitter under these conditions. Isolated measurements with a single-frequency input of 35,000 cycles indicated, however, that components of this order could be transmitted without serious loss and the subsequent performance of the system as a whole confirmed this conclusion.

It is well known that if a sinusoidal alternating current $i = I_0 \sin \omega t$ is modulated with a signal of

frequency $f = \frac{\Phi}{2\pi}$ the resulting modulated current may be represented by the expression:

$$i = I_0 \sin \omega t + \frac{k \ I_0}{2} \sin(\omega + \Phi)t + \frac{k \, I_0}{2} \sin (\omega - \Phi)t$$

where k is a fraction indicative of the degree of modulation. In other words, a modulated current, or wave, may be resolved into three components: (1) a steady component, known as the "carrier," which has the amplitude and frequency of the original unmodulated current, (2) an "upper sideband" which is equivalent to the signal spectrum with each individual frequency increased by an amount equal to the carrier frequency, and (3) a "lower sideband" which is an inverted reproduction of the signal spectrum, that is, each individual signal component is laid off in the downward direction from the carrier frequency, or, subtracted from it. Hence, assuming a carrier frequency of 1575 kilocycles and a signal input to the radio transmitter of the type described above, the antenna current, or the transmitted wave, may be represented diagrammatically as shown in Fig. 9.

It is evident that this type of radio signal can be received by employing an arrangement which will accept the entire band and subject it to rectification in the usual manner. If this is done, the television signal and the 30,000 cycle supplementary carrier modulated with speech will appear at the output of the detector. Branch circuits with suitable filters will enable these two components to be separated and the television signal passed on to the reproducing apparatus. The other component must be rectified to derive the original speech signal, which may then be impressed on the loud speaker amplifiers.

The reception scheme actually employed during the experiments was somewhat different. The television signal was received separately by means of the triple detection set employed for the demonstration. The speech signal was received in a similar manner employing the set utilized for the speech channel during the demonstration. This latter receiver was tuned to 1545 kilocycles. That reception in this manner is feasible, is evident from the diagram. The 1540-1550 kilocycle zone contains two speech sidebands and a carrier of 1575 – 30 or 1545 kilocycles. It is quite possible, therefore, to demodulate in one step, instead of "beating" the various components against the main carrier (1575 kilocycles) to produce a 30-kilocycle supplementary carrier which must be rectified a second time to derive the speech signal. The 1600-1610 kilocycle band was ignored. The receivers were sufficiently selective that, with the 5-kilocycle interval which existed between the two bands, no noteworthy crosstalk was experienced.

The results obtained in this manner were not as satisfactory as those to be had with the other system described. This can be attributed to two factors, both concerned with the transmitting apparatus: (1) In order to transmit both signals with the same transmitter, that is, the same vacuum tubes, the individual current amplitudes had to be reduced to at least one-half, resulting in too weak a radio signal to clear the prevailing noise levels in New York. (2) In spite of the reduced amplitudes, a certain amount of inter-modulation was experienced in the transmitter which resulted in "crosstalk" between the channels. Notwithstanding these deficiencies, however, it was possible to recognize the speaker and to understand his remarks; but a short time ago, the performance would have been considered a very noteworthy achievement.

Experiments of this nature, although not new, are of particular interest where television is concerned, since, as Dr. Ives has indicated, the logical trend of development is toward a finer picture structure involving the transmission of much wider frequency bands, or what is more likely, the use of parallel scanning schemes and multi-channel transmission. The work, while necessarily somewhat cursory, may, therefore, be of value in affording an indication of the significance of multi-channel radio transmission in this connection. From a popular standpoint, these tests have been described as the transmission of both voice and image "on a single wavelength." To what extent this statement falls short of actually representing the facts in the case is obvious from Fig. 9. It will be seen that a wider frequency band is actually employed with this system than was required for two separate channels. Furthermore, this wider band is much less effectively utilized. Two bands are required for the voice channel in place of one. At the receiver, one of these bands was disregarded. To have received both would have required apparatus accepting twice the band width and the gain in signal would have been offset by the corresponding increase in noise level. For all useful purposes, therefore, the energy radiated in the form of the second band is wasted.

To proceed further with a discussion of multi-channel radio transmission is beyond the scope of the present paper. Whatever the system employed, however, one conclusion illustrated by these experiments may be pointed to with confidence: Television by radio requires a discrete and fairly wide frequency band. Hence the frequently predicted introduction of television as an adjunct to radio broadcasting without extensive changes in existing channel arrangements is extremely unlikely.

Joints in High-Voltage Multiple-Conductor Cable

BY THOS. F. PETERSON[1]

Associate, A. I. E. E.

Synopsis.—*In this paper the author has outlined the evolution of multiple conductor joints and explained in detail the development of a three-conductor, high-voltage joint for use with belted and metal sheathed cables or combinations of these.*

In the final design, spreaders and barrier tubes have been replaced by specially reinforced crotches and hand-wrapped insulation.

To date, all tests,—short time and accelerated life, a-c. and d-c.,—have produced failures in cable rather than in joints so constructed.

Many other claims of superiority over existing types are presented.

* * * * *

LITERATURE on high-voltage cable theory, design, testing, and operation is remarkably voluminous. This fact is especially noticeable when comparison is made with the meager data available on joints or splices and characteristics of jointed cable systems. Only recently have questions pertaining to the last mentioned been treated or emphasized in technical papers and discussions. It is quite pleasing however, to note their appearance in papers such as Del Mar's on the Effect of Internal Vacua, and others on the use of reservoirs and design of joints. This paper falls in the same category as the latter and constitutes a presentation of data on design, installation, and operation of joints on high-voltage systems with which the author has been intimately associated.

In its final analysis a joint may be considered as a reconstruction of cable brought into being because it is physically impossible to maintain continuity of cable from one end of a feeder to the other. Most efficient design would dictate using a joint somewhat stronger electrically than the cable with which it is made. Except in a few cases, this is theoretically possible, although often it would appear as though "brute strength" tactics were used in its accomplishment. Single conductor joints, those in metal sheathed and braided cable with immense amounts of insulation and those in multiple-conductor cable of monstrous size, typify these. The evolution of joints, with improvements gained partly from experience and more recently by the application of scientific principles of design, constitutes an extremely interesting subject for study.

When viewed in its entirety, one notices that the trend in joint design has followed rather closely that in cable design and quite justly so, since joint construction is, in a sense, cable reconstruction. When the old Edison tube was in use splices were made in enlarged coupling boxes, these being filled with hard compound as was the tube. Following this, various types of taped and rubber covered cable were developed. However, joints were made as before, except for the introduction of barrier tubes. Increase in operating voltage then gave rise to changes in impregnating compounds. At the same time difficulties with voids in hard compounds which were unavoidably produced during filling and with charring of paper, necessitated the use of such filling compounds as petrolatum and the introduction of hand wrapping, still retaining the barriers, however. In more recent developments based on knowledge of cable breathing, migration of compound into cable, stress distribution, etc., oil and reservoirs have been used at joints, barriers eliminated, crotches reinforced and, from one point at least, it would seem that joint construction has overtaken that of cable inasmuch as very little oil filled cable has as yet been placed in operation.

It is quite evident that in old designs, creepage paths were considered as the most important factors determining dielectric strength, this probably being derived from experience with joints on d-c. systems in which moisture, condensation, poor workmanship, impurities and the like contributed largely to failures. There seemed to have been no regard for stress distribution, dielectric constant relations of insulating materials and so we find barriers, tubes, porcelain, mica, paper, compounds, etc., in series with one another in various proportions and placed indiscriminately in the electric fields. These statements are not intended to belittle the importance of leakage paths but rather to encourage consideration of all phases of design.

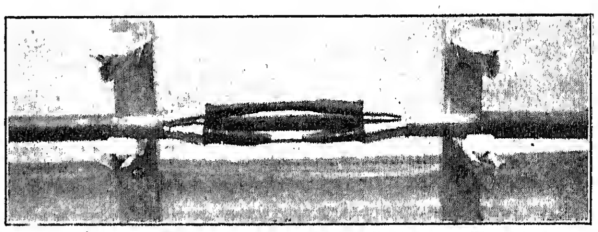

FIG. 1—METAL SHEATHED CABLE JOINT IN CONSTRUCTION

Quite general practise today consists in operating with alternating current and testing with direct current. Under alternating potentials at standard frequencies, the dielectric stress distribution is dependent on the configuration of electrodes and the constants of the dielectric circuits. On the other hand such distribution exists only at the moment of application of direct or steady potential differences. After this, redistribution takes place in the form of a slow transient with end conditions depending on the resistivities of paths. If then, total stress is sufficiently high, failure will occur along the path of minimum resistance. Though the

1. With the Brooklyn Edison Co., Inc.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

stress distribution under alternating current is determined primarily by dielectric constant relations, a component may always be determined acting in the direction of the leakage path and tending to produce this type of failure. It is obvious that the direct potentials with total voltage applied to path, are more severe. However, it is felt that defects brought to light by the comparatively high tests based on cable requirements are well worth removing and that the testing does not necessarily invite trouble. The importance of consideration of leakage paths as well as dielectric constant relations is thus brought out.

While the company with which the author is connected, was contemplating operation at 27 kv., many tests were made on multiple-conductor joints. Inasmuch as this was done under pressure of time no radical departures from standard types or accepted practises were made. Finally one, hand wrapped, petrolatum filled, with porcelain spreaders and mica barrier tubes was adopted. Results with this type were fairly satisfactory. After several years of operation, however, a rather high percentage of failures was experienced on test which, on examination, were almost all found to have started at connectors, then continuing along pencilling and conductor insulation or barrier tubes to ground. These were due to such causes as follows:

1. Copper dust produced by filing connectors.
2. Jagged pencilling of conductor insulation.
3. Wrinkled conductor insulation, (2 and 3 giving rise to voids).
4. Compound having been driven from mill insulation at pencilling by heat during sweating of connectors.
5. Migration of compound into cable, making most probable location of voids on contact surface between mill insulation and hand wrapping.
6. Sharp edges of solder, connectors, etc.

It is quite obvious why, with such causes as these conspiring to produce trouble, direct-current tests, at 95 kv., conductor to ground, and 135-kv., conductor to conductor, were so effective in weeding out defects.

The cures for these evils were soon found. Advances were made in cable manufacture (wrinkles being practically eliminated), pencilling was improved, one or two layers of varnished cambric tape was used over connectors, etc. These, with pressure filling, gave rise to a fairly satisfactory joint but, like "Champions and Records," this did not stand long, for tests at the laboratory under three-phase, alternating current revealed other weak places, namely, at the crotches and porcelain spreaders. Just about this time one company whose experience in this direction was very similar to ours began to experiment with wooden spreaders, the idea being that with a dielectric constant more nearly equal to that of impregnated paper better results would be obtained. Our progress was along different lines.

For some time manufacturers and those engaged in testing of cable had suffered a serious handicap in not being able to carry tests of three-conductor cable to satisfactory completion because of breakdowns which invariably occurred at the crotches. The author was confronted with and quite successfully solved this problem about 2½ years ago. Examinations of crotch failures of cable tested under oil indicated that there were three outstanding causes for these, namely:

1. Ruptured conductor insulation due to sharp bending.
2. Breakdown of film of oil and then paper at crotch.
3. Circumferential stresses on conductors.

The first was removed by fanning out legs in stages, that is, removing part of belt and bending legs, using edge of belt as a fulcrum.

The second did not yield so readily to the corrective measures applied. The attack was based on observations made during two tests devised to bring out the existance of this cause.

A roll of impregnated tape was used as a spreader in a crotch. After application of three-phase voltage, the roll was badly burnt due to breakdown of oil at its center. At another time a sample was prepared and the crotch placed in a glass jar of clear oil. Spark discharge across film of oil in crotch was very much in evidence.

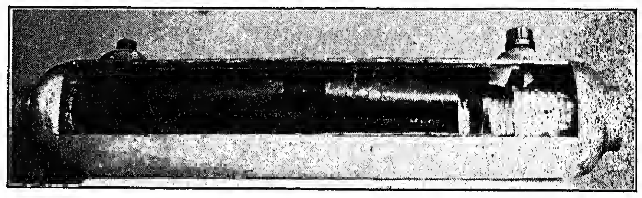

FIG. 2—CUT-AWAY OF JOINT IN BELTED CABLE

Joints of this type tested; 120-kv. three-phase, 10-65 hours.
Failures in cable; 130 kv. 15 hr. and 276 kv. instantaneous failure in cable.

The dielectric constant of oil is approximately 2.5 and that of impregnated paper 3.2 to 4.1. When insulations are in series in a dielectric circuit distribution of stress is in inverse proportion to dielectric constant. It is seen, therefore, why oil or compound was stressed beyond its rupturing strength, broke down, and the resultant heating, charring, etc., finally culminated in breakdown of adjacent paper[2].

Circumferential stresses on conductors manifested themselves by the appearance of tree formations at crotches through several layers of paper on the backs of conductors of certain types of cable, though these very rarely resulted in failure.

A rather simple solution for the above difficulties was arrived at after making some exhaustive tests using barriers, cotton, and the like jammed into crotches, short circuiting oil by wrapping legs with electrostatic shields, using wrapping of wick. Finally, after carefully

2. See author's discussion of paper on a 132-kv. joint, by D. M. Simons, presented at A. I. E. E. Winter Convention, 1927.

bending conductors, each leg was built up conically with black varnished cambric tape starting deep in the crotch and extending out 5 inches, the maximum thickness being 3/8 in., 4 inches from belt edge. (See Figs. 2 and 4.) The conductors were drawn together and a varnished cambric belt was applied at crotch to the level of the factory belt. Then the lead sheath of cable was extended, using lead foil, to the point of maximum thickness of varnished cambric. The lead foil and varnished cambric belt were punctured to allow oil to enter where normally fillers would be. With this type of construction, overstressed oil films at crotch were replaced with varnished cambric. The latter with its high dielectric constant (approximately 5) in comparison with impregnated paper (approximately 3) assumed very little of the total stress between conductors, but still took a sufficient per cent to relieve the paper at crotch and make the stress in it considerably lower than in the rest of the cable. The foil served to eliminate circumferential stresses by maintaining a zero potential surface at a distance outward from the center of the conductors equal to the distance inward to the actual neutral axis of the cable. Similar crotches were used in testing metal sheathed cables, except that after building up individual legs with varnished cambric the metallic tape of cable was extended and carried over each leg to the point of maximum thicknesses of varnished cambric (see accompanying illustrations).

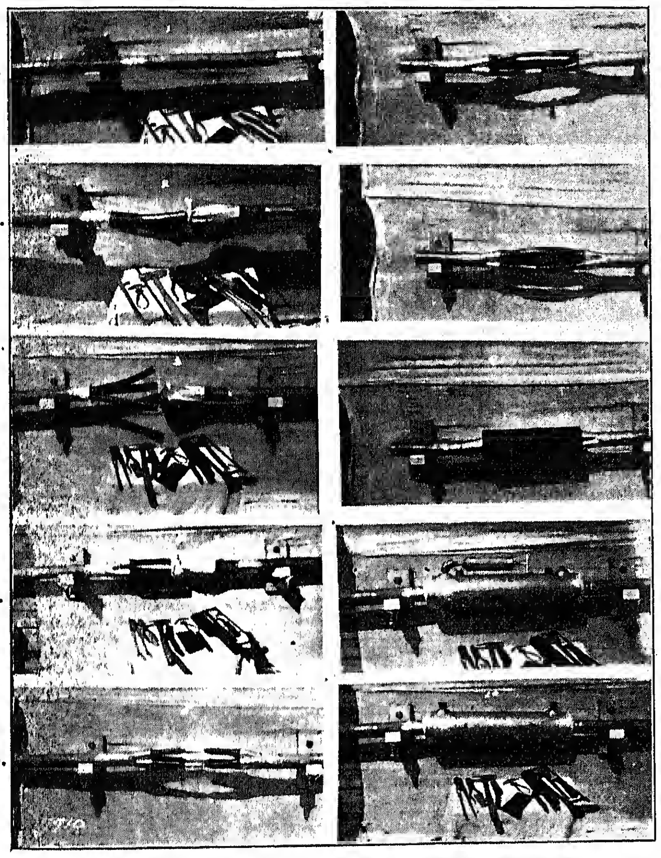

FIG. 3—SHOWING STAGES OF CONSTRUCTION

4. Crotch built up metal foil applied
5. Connectors sweated
6. Hand wrap
7. Hand wrap
8. Barrel slipped into place
9. Pressure filling
10. Caps on—completed joint

Results with this construction were highly satisfactory, yielding failures in cable after runs of 35 to 50 hours at 120 kv., three-phase as compared with 3 to 8 hour crotch failures previously obtained and so it was recommended for use in crotches of joints on our 27 kv. system. In the latter role, the applied varnished cambric served not only as a reinforcement, but also as pacer, thus eliminating another objectionable features of existing joint, namely, the porcelain spreader. (See Fig. 4.)

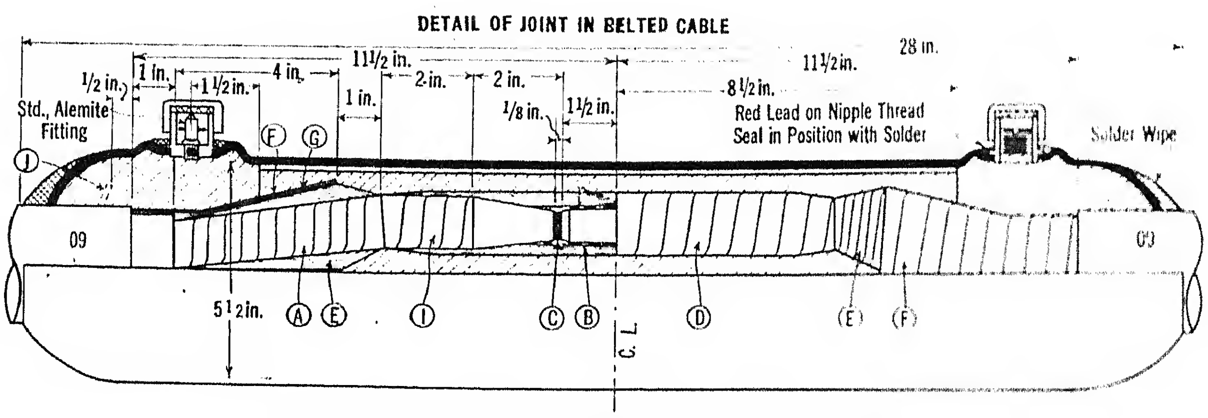
Before its adoption for use in connection with metal sheathed cable, comparative high-voltage tests were made on joints in which metal foil was ended at crotch, *i. e.*, cut off and tied down, carried across connectors, over hand-wrapped insulation, etc. In all these, the decided superiority of the built up construction was shown. Joints with metal tape carried across the hand-wrapped insulation failed after about twenty minutes at 120 kv., while those with tape ended at crotch were but a little better. In the first, failures occurred across stepped and conical penciling. This type of joint would seem unsatisfactory at first sight (despite the fact that some manufacturers stand by it because radial stresses are maintained throughout) since filling compound is of no avail in taking up stress and the total voltage is applied to a comparatively weak path between pencil and hand wrapped insulation. Joints made in manner described; that is, using built up crotches, have withstood tests at 120 kv. for 10 to 60 hours without failure. In all cases rupture has occurred in cable. This is quite favorable, when compared with the results obtained on standard Conducell joints which have averaged 3 to 10 hours at 120 kv., three-phase.

Hand wrapping of joints with tape has always been a long and tedious operation in which the personal equation of the worker is a most important item.

Prior to making the aforementioned studies and tests, an attempt was made to reduce manual labor involved in joint construction by substituting barrier tubes and spacers made of bakelite and the like, for the hand wrapping. Results of voltage tests were very discouraging since failures occurred at 120 kv. after from one-half to one hour, the higher values being obtained with the thinner tubes. Careful examination and investigation indicated that such devices which had high dielectric constants and were of such shape as to place small thicknesses of compound in series with them thus greatly overstressing the latter, were of no use and should be avoided. Barrier tubes were accordingly eliminated from final design (see Figs. 4 and 5) and some additional paper hand wrap was applied over connectors,

a very reasonable change, considering the facts that the paper serves as the necessary barrier in compound and makes it possible to retain comparatively long paths through compound thus increasing strength of joint, without over-stressing component parts.

Confirmatory test results similar to those recorded have recently been obtained by another of the metropolitan companies which has adopted this type of joint for metal-sheath cable. In addition to the above alternating-current tests, run of five hours duration at 95-kv., direct potential differences, conductor to ground, have been made without the slightest indication of any developing failure. These data, together with very satisfactory operating experience serve as evidence for claims of superiority of this joint.



A. One layer, 3/4-in., black varnished cambric on each conductor.
B. One layer, 3/4-in., black varnished cambric on each connector.
C. Varnished cambric strips 1/8 in. to 3/4 in. wide to level of connector diameter.

G. 5/8 in. lead foil two layers around all three conductors and in contact with outer metallic tape of cable.
H. Varnished cambric 5/16 in. thick 4 in. from bell.
I. Remove v. c. tape 3 1/2 in. from edge of pencil; also one layer of conductor insulation before applying paper tape.
J. Bell to be beat into original position after crotch is finished.

Fig. 5—Specifications For 3-Conductor, 27,000-Volt, A-09 Cable Joint, 27-3

Joints installed in practise do not differ materially from those described. Conductors are carefully fanned out and covered with one layer of tape to exclude foreign matter, crotches are built up, connectors are sweated, insulation pencilled conically (approximately 2 in. long) and sand-

papered. Then gaps between insulation and connectors are built up with thin strips of varnished cambric and one layer is applied over connector. One layer of mill insulation is removed from conductors and finally each leg is built up with hand-wrapped tape. An insulating barrel is used inside of lead sleeve, merely for mechanical protection and joint is either pressure filled with petrolatum, or oil filled and equipped with a collapsible reservoir or the like. Though this joint is somewhat more difficult to make than the usual type and depends quite largely on the ability of the splicer, little difficulty is experienced in the field, when men are properly trained.

In the foregoing we have been concerned more particularly with electrical rather than mechanical characteristics of joints. The latter, however, are of immense importance. Absolute cleanliness should be exercised. Wipes, plugs, and material must be such as to insure against introduction of moisture. Though voids are not likely to exist at time of filling, they may develop in practise, hence fittings, location in manholes, etc., must be arranged to facilitate periodic inspection, refilling of joints, or installation of reservoirs. These can best be dealt with as individual problems.

Summarizing, then, it may be said that a joint has been developed having high leakage resistance, good stress distribution and on which our test results, both alternating-current and direct-current, and operating experiences, are quite satisfactory. (Note: No studies have been made of dielectric loss because to date nothing in our experience has indicated the need for consideration of same.) Furthermore, barriers and spreaders have been eliminated and a zero potential surface has been established around the crotch which gradually extends out toward sleeve, thus tending to maintain radial stresses throughout joint. In addition, due to removal of tubes, phasing out of cables is more easily accomplished since conductors in joint do not have to be run parallel to cable. Instead of having two bends in the conductors one at each end of the joint, and then a straight run through cells or tubes as is necessary in the barrier type joint, the lay or twist may be continued through the joint. Last, and perhaps most important, is the universality of the joint. Not only can it be used with belted cable and metal sheathed cable, round or sector conductor, but also with combinations of these.

It is not intended that these statements be construed to mean that perfection in joint design has been reached. The author expects to attempt improvements from time to time and profit by criticism which will undoubtedly accompany its more general adoption.

Discussion

D. W. Roper: I am not going to subscribe to the implications in the paper that this type of construction is the only one that will result in successful high-voltage joints, but I can subscribe to the statement that single-conductor cable joints which are made up in essentially the same manner as the joints on each of the three conductors in Mr. Peterson's three-conductor joints, are very successful. In Chicago we have about 750 single-conductor joints made up very much the same as the individual conductors in Mr. Peterson's metal-sheathed cable joint; that is, they have the reinforcement of the insulation, the extension of the metal sheath to the point of maximum reinforcement, and then a tapering of the reinforcement as well as a tapering of the conductor insulation.

Mr. Peterson mentions the careful selection of materials, absolute cleanliness, and careful workmanship. In order to secure the latter two features in the single-conductor joints which we made, we started a school for the training of our cable splicers, using for the purpose a full-sized cable. We had each one go through all of the details process of making up a joint, or several joints if necessary, until he became proficient in the mechanical execution of the several processes.

To make sure that a man was proficient, after he had made up each joint, it was cut apart, and examined, and the imperfections in his workmanship were pointed out to him. He was required to repeat the process as often as was necessary,—generally only two or three times—until he had eliminated those imperfections in his workmanship. After that was done, we had him make up a joint at a different location where a high-voltage test transformer was available, and in order to secure economy, we had three joints made up in series putting high-voltage potheads on the ends of the cable and applying the high-voltage test required by the specifications to be applied to the cable. In each case, the failures occurred in the cable and not in the joints.

Since then, we have made up 750 joints on the 66-kv. cable and placed them in service, and have applied the usual high-voltage test to the completed lines before placing them in service. There have been no failures whatever on any of the joints, either during the construction training, or on the testing of them after the completion of the lines or in service. We have had a total of about 400 joint-years of service on this type of joint. So I think, as Mr. Peterson said, we are rapidly approaching the condition where joints are stronger than the cable.

E. D. Eby: In this problem of splicing high-tension cables, it is gratifying to note in Mr. Peterson's work an honest attempt to make use of scientific principles of design.

His adoption of the tapered reinforcement of conductor insulation adjacent to the lead sheath with the reinforcement overlaid with metal tape unquestionably constitutes one of the main factors in the success of his design. I advocated this construction to the Cleveland Electric Illuminating Company in 1923, when the 66,000-volt single-conductor cable system was first being developed. I think this was the first occasion on which this construction was proposed and described. How effective it has proved in the solution of cable-joint problems is evidenced by the fact that practically all of the higher-voltage joints have been made in this way and with a success which has been unparalleled.

A feature of which Mr. Peterson has not taken advantage, but which has worked out to complete satisfaction in General Electric designs, is that of stepped conductor insulation adjacent to the connector. Mr. Peterson found trouble with both stepped and penciled insulation in some of his designs but this was probably due to the use of inflexible paper tape. With a flexible tape such a bias-cut varnished cambric, there is a much better bond between the conductor insulation and the hand-wrapped insulation. The stepped surface, however, offers decided advantage over the penciled surface. An exact number of tapes can be removed at each step so that the remaining insulation is of a known and uniform thickness. Accidental cutting into the remaining insulation, as sometimes happens with a penciled surface, is thus wholly eliminated. The tearing of the tapes against a fine steel wire looped around the conductor leaves a spongy edge which fills well with the flushing compound and forms an elastic

cushion under the hand applied tape. The uniformity of the remaining insulation is particularly evident in the case of sector-shaped conductors where uniform penciling becomes even more difficult than with round conductors.

While, as Mr. Peterson remarks, it is true that the hand-wrapping of joints with tape has always been a long and tedious operation, it is also true that with the more scientific designs now available, the amount of taping to be done has been so much reduced and the kind of tape to be applied so much improved that hand-taped joints are not only wholly practicable from the installation standpoint, but are proving entirely reliable in service. Even machine wrapping of the tape does not offer sufficient advantage to warrant the use of machines except for paper tape. Furthermore, the introduction of the specially processed varnished-cambric tape with low dielectric losses has removed the one advantage of paper tape which formerly existed so that now a hand-taped varnished-cambric joint stands second to none, both with regard to ease of installation and its reliability.

While barrier tubes in three-conductor joints have proved disappointing in some designs, they are not an objectionable feature when properly shaped and located with respect to the conductors. The writer has developed a design for 33-kv. sector cable in which the barriers consist of sections cut lengthwise from standard Kerkolite cylinders, two such sections surrounding each conductor within an outer cylinder and holding it rigidly in definite relation to the other conductors and to the outer casing. The construction prevents displacement of the conductors within the casing which might occur either from short-circuit stresses or from mechanical movement of the cable.

In Mr. Peterson's joint for belted cable, he has found it desirable to enclose each conductor with an individual reinforcement of tape where it emerges from the belt. With no barriers to support the cables at the center of the joint, this serves a good purpose, mechanically. Electrically, however, it is not necessary, since a reinforcement enclosing all three conductors and overlaid with metal tape will accomplish the desired results. Sample joints tested by the writer have shown no weaknesses in the crotch.

Three-conductor cable of the belted type for 20,000 volts and above will probably give place sooner or later to cable of the shielded type so that future interest in joint design for three-conductor cables will center largely in the latter. It is natural that with each separate conductor enclosed in a metal tape under the lead sheath, a similar construction should prevail at the joint. Apparently Mr. Peterson did not have much success with such joints in which the tape was carried all the way across the hand-wrapped insulation. Here again perhaps the difficulty was with the kind of tape and a penciled rather than a stepped surface. At any rate, the writer has had no difficulty in making a satisfactory joint of this kind. Such a design for 33-kv. shielded cable is shown in the accompanying Fig. 1. The simplicity of this joint is at once apparent. The fact that each conductor is wholly enclosed within the grounded metal tape eliminates the transition made in Mr. Peterson's design from the equivalent of three single-conductor cables under the lead sheath to the equivalent of a three-conductor unshielded cable in the center of the joint.

That the totally shielded form of joint for three-conductor shielded cables is entirely practicable is further evidenced by the complete success of a 66,000-volt single-conductor joint of equivalent design. A further advantage in a totally shielded joint is the absence of immediate danger which results from an incomplete filling of the joint casing with oil or compound. In the open construction with oil between the conductors under stress, the absence of oil would be expected to develop trouble rapidly. In the totally shielded construction, providing moisture was excluded, an incomplete filling of the casing would not be serious.

Such descriptive papers as this will do more than anything else toward harmonizing ideas and unifying practise. There are certain fundamental principles in the design, installation, and operation of cable joints which this publicity will gradually help to establish. The standardization of materials and methods in this class of work is just as desirable as in other classes of equipment.

D. M. Simons: I should like to make a few remarks, particularly on the joints for Type-H or metal-sheathed cable. We have been making Type-H cable since 1914 (in commercial quantities since 1919), and have given the matter considerable thought. I approve of Mr. Peterson's solution, but I should like to point out that there is another solution.

I believe everyone agrees that one of the great advantages of Type-H cable is that all the so-called "crotch" failures can be avoided, since the metal can be carried into the joint until there is sufficient separation between the insulated conductors to avoid trouble. Apparently, however, there are two schools of thought on Type-H joints, differing in whether or not the metal foil should be carried completely across the joint.

We have made both kinds of joint, ourselves, having made those similar to the kind Mr. Peterson has described, with one refinement in addition; namely we used a large lead wire at the edge of the metal in order to reduce somewhat further the stresses there. The other form, which we have generally preferred, is to carry the metal shields across the joint. If this is done, then, theoretically, the joint has all the advantages of Type-H cable. Furthermore, and within the range of voltages where experience has not dictated the advantage (from the standpoint of the cable itself) of using soft or fluid jointing compounds with collapsible reservoirs, the carrying of the metal across the joint removes all stress from the compound, and there is no danger even if voids should exist. There is also of course no necessity for using reservoirs or otherwise maintaining the compound.

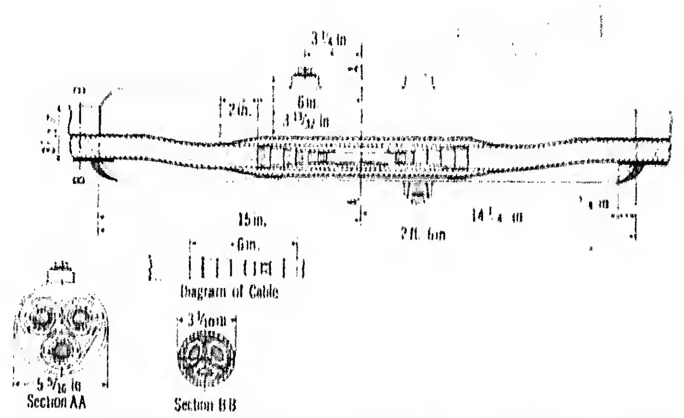

Fig. 1 33-Kv. 3-Conductor Joint for Shielded Cable

Finally, even if a soft compound or fluid oil is used for the sake of the cable, there is always a possibility that the joint may be partially emptied of oil due to the improper functioning of reservoirs or other causes; and in this case, there will be a great advantage if all the jointing compound has been shielded from stress by metal wrappings.

I do not hold a brief for either type, but wish to emphasize that there are two types available, both of which have been eminently successful in service. I believe in general that Mr. Peterson's type of joint, in which the foil is not carried across the joint, would probably tend to give better laboratory tests than joints in which the foil is carried across, because the stresses are lower. From the practical standpoint, however, I feel sure that the metal foil should always be continuous through the joint, if hard or fairly hard joint-filling compounds are used, and that in case of fluid compounds with reservoirs, both types of

construction should be carefully considered before a decision is made.

R. G. Hooke: At about the time Mr. Peterson started his development on high-tension cable joints, we were faced with a similar problem. Inasmuch as our solution of it is quite different from his, it seems that some of the details of the study which we have made and the results obtained may be of interest.

We first procured samples of several different types of three-conductor splices being used by various power companies. These were tested in the laboratory and at the same time careful

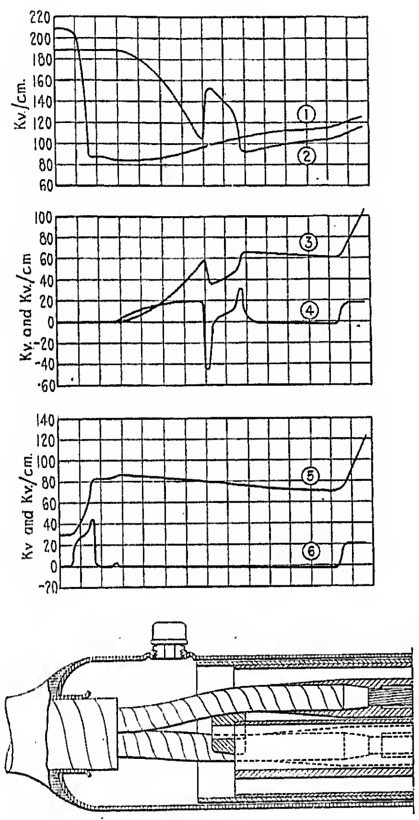

Fig. 2—Voltage Stresses in an Older Type of Cable Joint

Curve 1—Maximum Stress Toward Sheath in Factory Insulation Along the Corners of the Sector,—Kv./Cm.
Curve 2—Maximum Stress Between Phases in Factory Insulation Along Apex of the Sector—Kv./Cm.
Curve 3—Maximum Voltage from Surface of the Factory Insulation to an Instantaneous Neutral Plane Between Conductors—Kv.
Curve 4—Axial Stress Along Surface of Factory Insulation Between Phases—Kv./Cm.
Curve 5—Maximum Voltage on the Surface of Factory Insulation to the Nearest Point on the Sheath—Kv.
Curve 6—Maximum Axial Stress Along the Surface of Factory Insulation Nearest the Sheath—Kv./Cm.
Note: The Ordinate of Curve 4 is at all Points Proportional to the Slope of Curve 3, and the Same Relationship Exists Between Curves 6 and 5

analytical studies were made of the stresses which occurred in each. Mr. Peterson emphasizes the fact that in the past there seems to have been no regard for stress distribution or dielectric-constant relations of insulating materials and this was most certainly true in the majority of the specimens which we obtained. It would be impossible to agree too emphatically with the author's conclusion as to the harmful effects of porcelain spreaders, unreinforced crotches, and carelessly designed barrier tubes with high dielectric constants. By analytical comparisons, it is very easy to see the undesirability of such features.

In our work, we have developed certain methods, more or less empirical, for quick calculation of numerous instantaneous stresses in different parts of the joints and we find it very helpful to represent some of these by curves showing progressive changes in the conditions at different points in the splices, proceeding axially from one end toward the connector in the center. Illustrations of two of these charts will make their use clear.

The first illustration, Fig. 2, shows a joint in which conditions were particularly bad. The very rapid decrease in the maximum gradient to ground, as shown by Curve 1 at the termination of the cable sheath, is an undesirable feature. Also, the "bump" in Curve 2, caused by the presence of the porcelain spreader between conductors, is an obvious point of weakness.

The next illustration, Fig. 3, indicates a very considerable improvement. In this case, the major irregularities are due to the abrupt terminating of a static shield around the three conductors. Elimination of these discontinuities is obviously simple and curves result which are perfectly smooth except for conditions at the steps.

The irregularities on stepped or penciled insulation as shown in these figures require some explanation. The calculations are made along the surface of the original factory paper and therefore, at these points, abrupt increases of voltage necessarily occur due to the decrease in thickness of the factory paper and the consequent nearer approach to the conductor surface. These changes in potential cause the gradients shown, which are really in a radial rather than an axial direction; but they are plotted as part of the same curve as the axial stresses because they occur between adjacent surfaces of insulating material. Comparative effects of different numbers of steps or of different length pencils can readily be studied from these curves.

Of course the figures indicated on these charts are qualificative rather than quantitative, and of interest only in so far as they can be used for graphical indication of the differences between various designs of joints. However, when compared with the careful observations of conditions in the joints after the application on test of high potentials for periods of time up to several days, it was found that in a great majority of cases the weak spots were entirely determinable from analytic study made in advance of tests.

I mention these studies because I think that they emphasize the very great value of a scientific approach to the problem of cable jointing. In fact, so far as the electric field is concerned, splices are very much more complicated and require very much more careful mathematical analysis than does the cable itself wherein the assumptions of a homogeneous insulating medium can be made without appreciable error.

As a result of these studies a joint was determined upon in which the objective was to introduce as few foreign materials as possible. In other words, the more nearly we could make a splice an exact continuation of the cable, the better were we satisfied. With this in view, we concentrated our work upon joints insulated with hand-wrapped paper, the tape being carried well into the crotches at each end and cable compound being applied liberally during the operation. After the conductors have been insulated, the central filler space between the three conductors is filled with paper fillers, compound, and jute. We have found it desirable to fill completely the inside crotches of the joint with paper fillers saved from the outside of the cable after the belt has been removed, it even being possible occasionally to thrust one or two fillers back for an appreciable distance into the cable itself. The outer spaces between the conductors and under the belt are also filled with jute and compound. Jute has been used since it is not feasible to obtain paper satisfactory for this purpose.

At first our procedure was to also fill the spaces between the connectors and the factory insulation with jute. Recently, however, we have adopted the use of wrappings of narrow

varnished-cambric tape. In this connection, I am rather surprised at Mr. Peterson's practise of carrying the varnished cambric over the lower edge of his penciled factory insulation. He points out in numerous places the undesirability of having thin layers of low s. i. c. material in series electrically with rather heavier layers of high dielectric-constant insulation. It would seem from this consideration that he might experience an over-stressing of the edge of his penciled paper, where it is under the varnished cambric, this being also immediately next to the conductor and therefore at a point where the gradients are at a maximum.

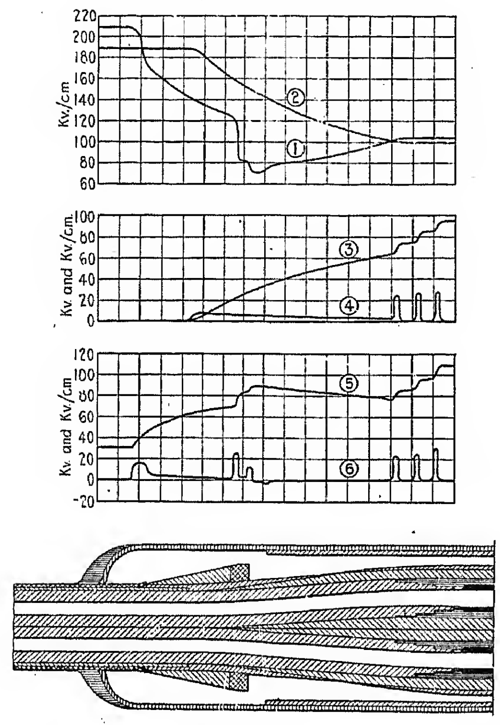

Fig. 3—Voltage Stresses in a Cable Joint of Recent Design

The Explanation of the Curves in this Case is Exactly the Same as for Fig. 2

We have found that our workmen were much more successful in making steps than they were in cutting a pencil. For this reason, therefore, although the pencil gives the best theoretical stress distribution, we have adopted three steps on each conductor. In making the joint, the varnished cambric at the end of the conductor is not allowed to overlap any of the paper insulation. It is merely used as a filler, its superiority over jute being mainly that it is a higher grade material and less likely to contain foreign particles or moisture.

A paper belt is applied tightly over the three conductors with the fillers in place and over this is used a copper screen which carries the ground-potential surface completely across the splice and is held snugly against the paper belt by a wrapping of heavy wicking. The joint is filled under pressure with a light oil or grease and expansible reservoirs are used. This splice as nearly as possible, is a continuation of the cable and depends entirely for its strength upon impregnated, homogeneous, fibrous insulation.

Perhaps the most important difference between our splice and Mr. Peterson's is our use of hand-wrapped insulating material completely across the joint, whereas in the central part of his splice he depends to a large extent upon the insulating value of the compound. The same feature is brought out in Mr. Peterson's remarks about joints on conductor-sheath cable; that he does not believe that it is desirable to carry the metal sheath of the conductors across the joint. He states that if the metal tape is carried across, the "joint would seem at first sight unsatisfactory * * * since filling compound is of no avail in taking up stress and the total voltage is applied to the comparatively weak path between pencil and hand-wrapped insulation." To us, this is by no means an obvious conclusion. In the first place, over the steps, the zero-potential surface in our joints, whether of the conductor-sheath type with the metal carried across the joint or of the belted type with the copper screen outside of the belt insulation, is very nearly identical with the lead sleeve of the joint. In other words, there is very small clearance between the lead sleeve and the built-up insulation about the splice. Therefore, unless Mr. Peterson uses a larger diameter of sleeve than ours, the leakage path in his joint, either from the connectors to the ground surface or between conductors, is practically the same as it is in ours. The reduction in the length of this path due to the use of the screen about the conductors is exceedingly small. Secondly, there is one very important point in dielectric circuits which it seems to me Mr. Peterson does not sufficiently emphasize. It has been proved conclusively by a number of authorities that the breakdown strength of oil in volts per mil is very much greater for a thin film than it is if the material is not broken up into such films. Mr. Peterson accomplishes this division of the oil into films in his reinforcement of the crotch with varnished cambric, although he speaks of it as simply a replacement of the compound by a higher-strength material. It is actually both of these. However, the filling in of the space which he leaves free for compound between layers of fibrous insulation, in the middle of his splice between which would be distributed liberal amounts of oil or grease, should result in a definite increase in the breakdown strength of the joint at this point. As a matter of fact, some rather hurried and incomplete tests which we have made indicated that a direct puncture can occur from the connector to the sleeve on a splice made up as nearly in accordance with Mr. Peterson's design, as we are able to produce it, whereas, on numerous tests, no fault of this type or any other has ever occurred on joints of the kind which I have described and which we have adopted. The failures are invariably in the cable.

There are one or two questions which I should like to ask the author. He states that the cambric belt is punctured to allow oil to enter the cable where the fillers would normally be. Inasmuch as he does not carry the belt completely across the joint, we wonder that this puncture should be considered necessary. It would seem as if the compound would fill all of the spaces under the belt by entering through the empty filler spaces. Possibly his real objective is to provide an outlet for air bubbles which might collect under this belt insulation. Even this, however, would seem hardly necessary unless one end of the joint was appreciably higher than the other when it was being filled. The use of the static shield outside of the belt reduces to a safe value axial and circumferential stresses which might otherwise be harmful. We question, however, whether or not this shield *eliminates* the circumferential stresses in belted cable as is claimed. It certainly does maintain a zero-potential surface at a distance outward from conductors which is nearly equal to the distance from each conductor inward to the cable axis. This axis, however, for purposes of stress determinations, is not a zero-potential line. True, its *average* potential is zero, but at any instant its potential may not be zero. For example, assuming the three conductors to be carrying three-phase potential, if at a particular moment, the voltage of one conductor is zero, the voltages of the other two conductors will be opposite in sign and equal to 86 per cent of the crest value of the wave. Certainly, the geometric center of the cable would not then be at zero potential and for the moment, circumferential stresses about the conductors would exist. Determination of the magnitude of these stresses in a joint on sector-conductor cable

using different types of splicing materials is exceedingly difficult. The fact seems to be that Mr. Peterson, by keeping his ground-potential surface nearer (than in the older joints) to the conductors, as each conductor is gradually moved away from the other two, has reduced the circumferential gradients to values which do not cause trouble; but these stresses are reduced only by virtue of the gradual transition from cable diameter to splice diameter, which is accomplished by the shield, the rate of transition being determined by the rate of separation of the conductors from each other.

We are inclined to question the author's reference to Conducell joints. We believe that the design of the Conducell barrier is excellent, if barriers are to be used at all and we should like to know whether or not Mr. Peterson tried reinforcing the crotches of the Conducell joints in the same way that he does his standard splice. We should expect this to improve greatly his test results on these joints.

In conclusion, I wish to say that the work which Mr. Peterson has done is extremely valuable. His joint is not difficult to make and it possesses a large number of very praiseworthy features. To me, one of the most interesting of these is the idea of a design which permits application of most of the hand-wrapped insulating material before the sweating of the connectors. With the ends of the conductors open, it should be very much easier to apply the insulation and also accomplish a considerable saving in time.

F. A. Brownell: We have tested a number of the author's cable joints between metal-sheath cables and between metal-sheath cable and belted cable, and have had one failure in the metal-sheath cable joint.

In each of the metal-sheath joints tested, evidence of overstressing was indicated by carbonized petrolatum at the end of the metal shield over the varnished-cambric cone and evidence of ionization at the lower edge of the cones.

In the joints where metal-sheath cable was joined to belted cable we found some evidence of overstressing at the surface of the conductors. This type of joint appears to be the best that has been offered for this type of construction.

We have been using the idea of the varnished-cambric cones for the past three years in making end-bells for testing cable in the laboratory, the only difference being that we apply two half sections of lead foil over the formed cone. We find that these sections can be applied in less time and eliminate more voids than the wrapping of narrow widths of foil.

Our test data on joints where the metal tape has been carried entirely across the hand-wrapped insulation are not in agreement with the author's. We have made numerous tests on this type of joint in the laboratory and have never broken down a joint nor opened one that has shown any indications of having been overstressed. In one test, failure occurred in the cable after 24 hours of testing at 125 kv. Another test at the same potential lasted for 20 hrs. with the failure in the cable. These tests do not compare with the author's test of 20 min. at 120 kv. Of the hundreds in service we have very recently had two failures.

To compare a joint for belted cable, we have tested and are now using the nearest thing to cable reconstruction that we believe is possible,—an all-paper joint with jute fillers, gauze stocking for shielding, and filled with the same oil as is used in the cable. This joint was designed a few years ago by Phillip Torchio, of the New York Edison Company, and is known as the Metropolitan joint. We have never broken down one of these joints on test. In one case we held 132 kv. for 25 hrs. when the cable failed. No evidence of overstressing was found in the joint.

We do not think it necessary to maintain the lay of conductors through the joint and we believe that another step in the art will be accomplished when phasing-out in manholes is eliminated.

J. F. Fairman: During the past five years an energetic program of cable and insulation research has been in progress in the Brooklyn Edison Company. The results, though by no means final or complete, have been very gratifying as reflected in the marked improvement in the performance of cable in operation. This improved performance is due both to better manufacture and to refinements in handling, jointing, testing, and maintaining cable by the operating company.

Mr. Peterson has discussed one of the more important contributions to improved operation made by the operating company in describing the evolution of our joint for multiple-conductor, high-voltage cable. I believe it is pertinent at this time to mention briefly another very important feature in this progress,—the installation of oil reservoirs on these joints.

In 1922 in the early stages of the redesign of the transmission system of the Brooklyn Edison Company, it was determined to make 27,000 volts the basic transmission pressure for future developments. Before placing this system in operation however, a great deal of consideration was given to the various factors of cable design and method of jointing and testing cables. Three fundamental factors essential to good performance of a cable system were brought out in this analysis: (1) Thorough initial impregnation; (2) a means of assuring against the formation of voids after installation; and (3) the prevention of entrance of moisture. Good cable could be had at the factory and careful handling gave reasonable assurance against oil leakage and the entrance of air and moisture, but after a cable is in operation with the inevitable cycles of heating and cooling, there is migration and absorption of the compound which, although very slow, produces voids. Vacua of considerable magnitude have been found in cable, and any breaks in the lead sheath or imperfections in the wipe at a joint will allow air and moisture to be drawn into the cable or the joint.

As a result of this analysis, the Brooklyn Edison Company, at the initial installation of 27,000-volt cable in 1922, adopted the policy of installing oil reservoirs on the cable system in the hope of insuring a positive internal pressure above atmospheric pressure throughout the cable system at all times. It is obvious that with such internal pressure and a supply of oil for filling in voids, a break in the sheath would result in bleeding rather than the entrance of air or moisture. Loss of oil in this way could be detected by inspection of the reservoirs.

Such reservoirs were first installed in the stations at transformer and switch potheads. It was found that the migration of oil throughout the cable was so slow that these reservoirs on the potheads were not sufficient to maintain a positive pressure throughout any great length of cable. The next step was to install such reservoirs on a few feeders at the cable joints in the manholes, and the results obtained were so satisfactory that this practise is being extended gradually to the whole 27,000-volt cable system.

Two examples will serve to illustrate the results obtained. One feeder of old cable which had had a fairly good record as to failures, was taken out of service during a period of rearrangement. On testing it before putting it back into service, a number of failures both in cable and in joints, as well as the dry condition of the paper in the sections examined after failure, led us to make an experiment on this feeder. Oil-filled reservoirs were connected to each joint and it was put through periodic heating and cooling cycles for one month at low voltage and 150 per cent rated current. During this process 27 gallons of oil were absorbed, which is approximately equal to 1 per cent of the original compound in the cable. Then the feeder was tested. It went back into service without a failure in the cable, and has been operating steadily ever since. Another old feeder gave so much trouble that the operating voltage had to be reduced to 13,000 volts. Each joint was then equipped with a reservoir filled with oil and operation at 13,000 volts was continued for six months. Following this, it was tested for 27,000-volt operation and has given very satisfactory service at this voltage for over a year. To date 72 gallons of oil, which is approximately 2.6 per cent of

the original compound, have been absorbed by this feeder from 120 reservoirs.

W. F. Davidson: Mr. Peterson has called attention to the tests which were made to determine the merits of joints in which metal foil was carried across the connectors and those in which it was cut off at some distance back from the connection. This suggests a point which seems to have received too little attention in connection with cable and joint specifications.

The significance of this was not appreciated until after considerable experimental work had been done. In the early stages it became evident that in order to secure prompt results it was necessary to use cable of superior quality so that the failures would occur in the joint rather than in the cable. However, when field construction work was started a new factor became noticeable.

The ideal condition in a joint or terminal, or for that matter in the cable itself, is to secure strictly radial stresses in the insulation which is under stress. But it is not always possible to do this in joints and terminals. Consequently, we are faced with the necessity of meeting more or less severe longitudinal stress. In their ability to withstand such stress, various cables show extremes of performance. I think it quite safe to say that the range of values obtained under these conditions is far greater than the range obtained with respect to radial stress. As an example, during some recent test on several samples of cable of the metal-foil type, it was found that with an end prepared in the manner described by Mr. Peterson, one sample could be operated for barely 30 hrs. at 120 kv. between conductors before failure occurred and even when it was possible to get failure of the cable under the lead, the ends almost invariably showed signs of severe longitudinal stress. In contrast to this, another sample of cable prepared in the same way and having the same insulation thickness, has operated for over 640 hrs. at 120 kv. without showing the slightest signs of stress.

Mr. DelMar has called attention to surface-tension effects and these probably explain some of the differences just noted. We might expect therefore to reduce troubles of this nature by making sure that the compounds used to fill the joint or terminal were of exactly the same character as that used in the cable itself so as to make a minimum surface tension along the boundary between the cable insulation and the surrounding medium. However, there are obvious and serious practical objections to such a procedure and it seems absolutely necessary to find some other solution to the difficulty.

Summarizing, I wish to urge the need for "jointable" cable. That means not only cable which can stand up under the bending and working essential to making a joint or attaching a terminal, but cable so constructed and impregnated that it has longitudinal as well as radial dielectric strength.

Herman Halperin: About two years ago tests were made in Chicago with the crotch of a 33-kv., three-conductor (sector) cable placed vertically in clear oil in a glass jar with a copper screen at ground potential inside the jar. The observations corroborate those made by Mr. Peterson in that spark discharges were observed across the film of oil in the crotch; but before this occurred, streamers were seen along the tape edges just above the end of the belt insulation. Some of these streamers ran around the conductors. It was found that such discharges could persist for about an hour at 120 kv., three-phase, without leaving visible signs of deterioration in the insulation, and before discharges across the oil in the crotch were noticed. It was also observed that bubbles of occluded air or other gases, which were seen clinging to the insulation previous to the application of voltage, would become dislodged upon the application of the voltage and flow upwards.

In the last page of Mr. Peterson's paper, it is stated that the joints were filled with petrolatum or oil. Experience in Chicago with petrolatum in three-conductor, 33-kv. joints has been unfavorable. About three years ago some 75 three-conductor 33-kv. joints filled with petrolatum at atmospheric pressure were installed. During the following winter several failures occurred in the crotch of the joints. The petrolatum was full of small voids or air spaces the size of a pinhead and had pulled away from the factory insulation of the conductors, causing void spaces around the conductor insulation in the crotch. Apparently the petrolatum contracted on cooling and pulled away from the mill insulation, and the maximum operating temperatures of about 20 deg. cent. were insufficient to melt the petrolatum which had a melting point of 30 deg. cent. Therefore it appears that if a hard or semi-hard compound is used its properties of adhesion to the cable and cohesion should be carefully chosen.

When these joints were rebuilt, they were filled with a thin oil (switch oil) and they gave entirely satisfactory service for the seven months when they operated at 33 kv., although in rebuilding the crotches were not reinforced.

Some experiments were recently started to reinforce the crotches on 500,000 and 650,000-cir. mil, three-conductor, 13-kv. joints. These cables have 9/64-in. insulation around each conductor, which is less than half the insulation on the cable used by Mr. Peterson, and the conductors are considerably larger and stiffer than his conductors. These joints are to be filled with an asphaltic compound that has a Saybolt viscosity of about 750 sec. at 100 deg. cent., but to eliminate the variable introduced by the differences in filling obtained with the semi-hard compound used, oil was employed in these experiments.

The first joints were made with varnished-cambric tape applied around the conductors in the crotch in a fashion similar to that used by Mr. Peterson except that the foil was not used and, in addition, varnished cambric was applied around the three conductors. These joints were tested at 4.5 times the rated voltage for six hours, after which 10 per cent geometric increases were made every hour. The test results have been evaluated for the equivalent voltage for six hours. The joint with no reinforcement failed at nine hours, which test was equivalent to 69 kv. for six hours, using the 7th-root relation that has been developed for breakdown voltage time characteristic of impregnated paper insulation. The corresponding voltage for the joint with the reinforcement was 75 kv., an increase of 10 per cent, but still failures were obtained in the joint. The failures were found in the crotch region at the end of the belt.

Later, insulation was applied to the conductors only and this was done either before or after the connectors had been sweated. In the few tests that have been made, the joint with the reinforcement applied before the copper sweating has been found to be the stronger. The equivalent voltage for this joint for six hours is about 90 kv., which is 30 per cent better than that found for a joint with ordinary construction.

The fillers were left extending 3 or 4 in. into the joint, and after insulating, a couple of turns of twine were wrapped around the three conductors to hold the fillers in place. Cutting fillers, especially the central one, close to the end of the belt is liable to result in damage to the conductor insulation.

In the discussion of Mr. Simons' paper in the Winter Convention, Mr. Oesterreicher presented* some data on the beneficial effects of flared-out shields applied at the cable lead; and I am wondering whether Mr. Peterson has used anything of that nature on three-conductor joints.

The experience of the Commonwealth Edison Company is in thorough accord with the statement at the end of the paper, that such a joint (or any high-voltage joint) "depends quite largely on the ability of the splicers," and that "little difficulty is experienced in the field when men are properly trained."

A. H. Kehoe: Unanimous agreement will not be had to the statement that a decided improvement has been made over types of joints previously used.

It seems desirable to emphasize that only operating results in service are conclusive and that high over-voltage test methods

*See p. 245.

may be wrongly interpreted. My experience with joint operation is that failures due to poor workmanship, several types of which are mentioned by the author cannot be ignored. One of the most common causes of failure in operation apparently has been omitted; that is, "leaky wipes." Such workmanship defects are now the principal cause for joint failures but, as stated by the author, compound-filling arrangements have reduced the number of these failures.

It does not seem wise to adopt a type of joint which requires very superior workmanship to make it successful, as compared to one in which ordinary careful workmanship will eliminate failure in service. This is likely to take place when high-voltage test results are used exclusively as a criterion for successful joint operation. They assume that factors of safety for all joint elements should have the same value, which is not required, particularly where the factory-formed type of joint insulation is one of the elements. The advantages of factory-formed insulation (the author mentioning Conducell, a well-known joint of this type) are evident in statistics of operation, and testing methods which give stress values beyond the breakdown values of certain of the elements do not demonstrate what the operating results will be if such values are never encountered.

Mention is made of the experiments with wooden spreaders. I can report on this that removal of all spreaders has resulted in a satisfactory mechanical joint and has eliminated an unnecessary element.

The author refers to confirmatory tests for metal-sheath cable which appear to be those made by the company with which the writer is associated. For joints on the metal-sheath type of cable, we have used a joint similar to that described in the paper. At present we know of no better way to make such joints, although possibly some improvement will be forthcoming which will reduce the workmanship hazard now ever present with the hand wrapping of three-conductor joints.

For the belted type of cable we doubt if operating results will show improvements over the factory-formed type, and so are continuing to use the latter. Experience has shown that both the time of making joints and their cost will increase by adopting the type suggested.

T. F. Peterson: Although practically all features of the joint described, together with the bases for design, have received favorable mention by one or another of those contributing discussion, there seems to be no general concurrence of thought or opinion. Possibly this is due to the fact that many have felt the call to defend joint designs with which they have had experience and there has been agreement of thought in just such measure as their designs are similar to the one in question.

Mr. Roper's report on the successful operation of single-conductor joints made up similar to the individual conductors of the joint described is very interesting and gratifying. His description of splicer's schools is quite timely and should serve to impress the importance of systematic training of men in the art of joint construction.

Mr. Eby has brought to our attention his early use of reinforcement of the insulation at the edge of lead sheath of single-conductor cable, overlaid with metal tape. While this means of relieving stress is highly commendable, it is felt that the use of varnished cambric (obtaining advantages of high strength and dielectric constant) instead of impregnated wick or cord, together with its use on three-conductor cable, is an advance. He feels that building up individual conductors of three-conductor belted cable is unessential electrically and cites his experience. This is not in accord with the results presented in the paper by me or in the discussion by Mr. Halperin. I dare say that the use of built-up crotches of test sections in many laboratories, including the Electrical Testing Laboratories, is based on some such observation as the last mentioned.

Undoubtedly the combination of low-loss varnished-cambric tape and stepped insulation described by Mr. Eby is a very good one and might supplant the use of paper tape and conical pencil. However, difficulties with the latter are not so great as intimated. The work is rather quickly and quite accurately done, using a sharp knife and sand paper. The resulting surface is rough and when insulated presents no abrupt changes or finite discontinuities. Low-loss varnished cambric is a comparatively new development, and although it possesses many advantages, its use may not become general until there is more than one source of supply. This is the situation which dictates certain practises despite technical data pointing to the contrary.

The use of barriers for electrical reasons will be discussed later. At this time suffice it to say that in the joint described they are not needed for mechanical stiffening. Short-circuit tests of 20,000 amperes for several cycles have resulted in no appreciable movement of conductors.

Whether the tape of metal-sheath cable should be continued through the joint or not is a matter of concern to many. The reasons for maintenance of it are variously stated; for example:

1. Since the cable is so made—the joint should be.
2. Abrupt discontinuities and transitions are eliminated.
3. Voids may exist or the joint may drain without harm.

The first has no particular justification except in so far as there are incidental advantages which may accrue. The second is accomplished fairly well in the joint offered. As for the third, if voids in compound are expected, by all means short-circuit them. However, in the case of joints which may drain,—that is, lose their oil,—since these will probably fail eventually due to water, drying out or the like, this joint offers very little in favor of carrying the tape through. On the other hand, if conductors can be satisfactorily insulated with tape only, it would seem quite possible to cut down on hand wrapping when oil is brought into use. At least, the entire burden will not be placed on hand wrapping (with its uncertain personal element) but some part will be sustained by the oil.

Mr. Hooke has presented some very interesting data and ideas on joint design, stress distribution, and dielectric circuit theory. The joint which he describes seems to be identical with the so-called Metropolitan type inasmuch as both are largely re-builds of cable. As such, considerable dependence is placed on the hand-made elements of the joint and as Mr. Kehoe points out, this is not always very desirable. In the early work in Brooklyn an attempt was made to eliminate hand operations entirely by insulating conductors with oil and barriers. When this failed, joints such as described were evolved. In these, the human element or personal equation is quite important so far as the hand wrapping is concerned. However, the oil serves as a second line of defense and renders inconsistencies in this less important.

Though Mr. Hooke has found a use for the Brooklyn Edison Company idea of thin strips of varnished cambric between connector and penciled mill insulation, he criticises the over-lapping of the latter with the tape and quotes my statements on the undesirability of having short paths of low specific inductive capacity material in series with long paths of high specific inductive capacity material. He has apparently overlooked the fact that in determination of stress distribution or values of gradients, the entire path from electrode to electrode must be considered to determine flux densities. These, multiplied by 1/s. i. c., give gradients. Obviously, a little varnished cambric (high s. i. c.) over a short path of mill insulation but having in series large amounts of oil, paper, etc. (low s. i. c.) cannot greatly alter the stress in the penciled insulation.

He also questions the use of a conical shield over the crotches of three-conductor belted cable, in eliminating circumferential stress. The basis for his argument is an attempted proof that the cable axis is not at zero potential. Given homogeneity and symmetry of position this must be the case when three-phase voltage is applied. I am at a loss to understand the reasoning

in the case cited. When one conductor is at zero potential and the others at plus and minus 86 per cent of maximum potential, the locus of the zero-potential points is a plane half-way between the two conductors and perpendicular to their line of centers. Certainly the geometric axis of the cable falls on this.

Barriers in oil may be considered to produce beneficial results in two ways:

1. Where the free path in oil is broken up so as to reduce the distance in which ionization by collision may take place thus greatly increasing gradient for breakdown; for example, paper and impregnating oil.

2. Where paths are long and breakdown is due to lining up of ions—water, impurities, etc.—barriers prevent this action and so increase the over-all strength.

There remains a range from approximately $\frac{1}{4}$ in. to about 2 in. in which the use of barriers is questionable. Their s. i. c. is usually high and since their thickness may be no small part of the total path of electric flux, the incidental shifting of stress in oil may more than overcome the advantage of barrier action. In view of this and since operating experience indicated that they were very ineffective in preventing failure where moisture or poor workmanship were present, barriers were eliminated entirely from the joint described. The breaking up of the oil space into very short paths, as is done in the Public Service joint by the use of filling materials, is quite permissible, although one might question whether this done under unfavorable conditions will furnish much of an improvement over the use of good oil.

I also doubt if many will subscribe to Mr. Brownell's idea on the elimination of phasing-out in manholes, although it would seem that this is greatly to be desired in view of the introduction of isolated-phase construction, installation of networks, etc. At any rate, does it not seem advantageous to phase out in joints (rarely ever more than one in any one location) rather than subject one cable end at the pothead to twisting each time there is need for change?

Mr. Davidson's remarks are a fitting supplement to a paper on joints. Regardless of the type of cable or joint, the introduction of longitudinal stresses is inevitable at the pothead if at no other place. I join with him in a plea for a cable better able to withstand these stresses.

In response to the queries of Mr. Halperin I might say that due primarily to migration, considerable difficulty had been experienced with petrolatum-filled joints, but periodic refilling (at six-month intervals) almost entirely eliminated this trouble. As for the use of flared metal shields at crotches, several of these carefully made of spun brass were tried but the results were no improvement on those obtained with metal tape laid on the built-up conical structure.

The Use of High-Frequency Currents for Control

BY C. A. BODDIE[1]

Associate, A. I. E. E.

THE rapid development of radio has given rise to a parallel development in the art of remote control. Remote and supervisory control is being applied to an ever increasing variety of problems. This control is now commonly effected by the use of special wires connecting the apparatus under control with the point from which control is exercised.

Wires suitable for control purposes are often difficult to obtain. If they are supported for any considerable distance on the same towers as the power line, induction from the power line may seriously reduce their value unless special measures are adopted. If the wires are carried on separate poles on a separate right of way, the cost becomes a formidable item. The other alternative is to lease the necessary circuits from the telephone company. In this case, the rentals are always so high as to be a serious burden on the whole project.

The expense of obtaining and difficulty in operation of special wire circuits have directed attention to the possibilities in the use of alternating currents of moderate or high frequency for control purposes. The object has been to utilize the existing power conductors as a control circuit. This has been accomplished by superimposing on the live power circuit a frequency sufficiently different from the power frequency to permit its being easily separated from the power frequency by suitable tuned circuits. Although this current flows in the power system together with the power current, it is independent of it. It may therefore be used for control purposes.

The application of alternating current to control problems opens up many new fields. The development of apparatus is already quite well advanced. Some of the equipment has been in commercial service for over two and one-half years and has given good account of itself. The applications already developed provide for the control of large main line oil circuit breakers, substation apparatus, and street lights. It is expected that this type of control will be used quite generally for all classes of control now requiring special circuits, where these circuits introduce a serious burden on the project as a whole.

The development has been carried out along two rather distinct lines. The apparatus may be classed according to the frequencies employed as

1. Medium-frequency systems,
2. High-frequency systems.

The medium-frequency system employs frequencies of the order of 500 cycles. This control frequency is so low that it passes through transformers just like power frequencies. The control frequency is generated by a motor-generator set and is fed into the circuit usually by means of condensers. The special advantage of this system is that the line losses are low on account of the moderate frequency used. It is possible to transmit sufficient energy to the receiving devices to directly actuate a relay magnet. This relay is tuned to the control frequency and therefore responds only to this frequency. The relay is simple and sturdy and requires no vacuum tube amplifier. The system is very flexible and is well adapted to quite a variety of applications.

The high-frequency system employs frequencies of the order of 50,000 cycles. Frequencies of this order are most readily produced by vacuum tubes. The energy employed in the high-frequency system is much less than that required in the medium-frequency system. Vacuum tube amplifiers are necessary to amplify the control frequency at the receiving point in order to get sufficient energy to operate a relay satisfactorily. On account of its requiring vacuum tubes, the receiving equipment is much more bulky and more complex than the corresponding equipment of the medium-frequency system. Currents of this frequency do not pass readily through transformers. Its application is therefore limited mainly to operation over high voltage power lines, but it is well adapted to this class of service.

HIGH-FREQUENCY SYSTEM INSTALLED AT TIPTON, INDIANA

Sporadic attempts at control utilizing radio or high-frequency currents over wires date back over a period of 10 or 15 years. These attempts assumed more of a spectacular than of a practical trend. Perhaps the first definite attempt to control the apparatus of a power system by high-frequency currents was made just previous to the opening of the Dresser Power Station of the Central Indiana Power Co. There was then in operation a high-frequency system controlling two 66-kv. circuit breakers at Tipton, Indiana. The control point was Kokomo, Indiana, some 20 miles distant. The 66-kv. line loops through the substation at Tipton. An oil circuit breaker is installed in each branch of the line as it connects to the high-tension bus at Tipton. This is indicated in Fig. 1.

The local power plant which previously supplied the town of Tipton was shut down shortly after the transmission line was built between Indianapolis and Kokomo and power was supplied from the line. The substation at Tipton is about a mile out of town. An operator is not maintained at this point. The object of installing the circuit breakers and the control system was to insure continuous service to the town from either of two power sources, namely, Indianapolis

1. Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

and Kokomo. In case of line trouble on either side of Tipton, the section in trouble could be cut clear by operating the proper breaker at Tipton and the town supplied with power from the remaining section of line. The absence of an operator at Tipton necessitated the installation of the control system.

At the time it became apparent that supervisory control of the Tipton breakers would be desirable, an

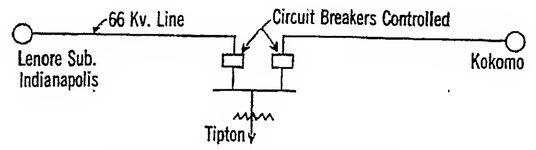

FIG. 1—SCHEMATIC DIAGRAM OF CIRCUIT BREAKER INSTALLATION AT TIPTON, INDIANA

efficient high-frequency telephone system was already in regular operation over the Indianapolis-Kokomo lines. It was decided to use the transmitter then installed at Kokomo and to install one of the standard receivers and calling selectors at Tipton for the operation of the Tipton circuit breakers. A special frequency was selected so that there could be no interference between the telephone system and the control system. This special frequency could be readily produced since the Kokomo transmitter was already

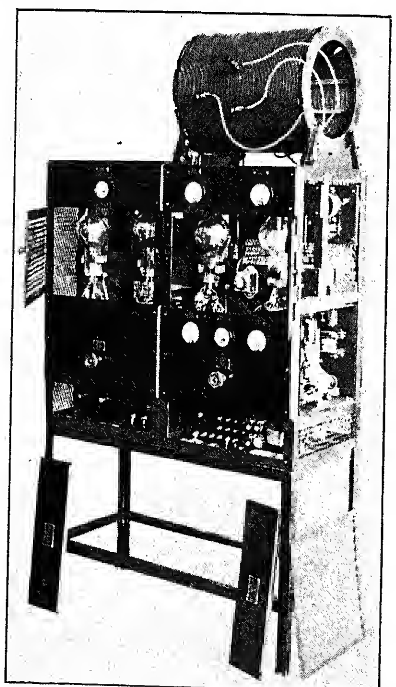

FIG. 2—TYPE OF TRANSMITTER INSTALLED AT KOKOMO
This transmitter is rated at 250 watts and is used for both control and telephone communication

provided with a wave-change switch as a regular part of the equipment, whereby its frequency could be changed from the normal frequency used in telephone service to any other desired frequency. The operation of changing frequencies was accomplished by the operation of the automatic calling dial.

HETERODYNE RECEPTION

The receiver was of the usual coupled circuit type as shown in Fig. 3. The receiver circuits employed were exactly the same as used regularly in the telephone calling system. This utilizes the well-known heterodyne method invented by Fessenden for radio telegraph reception. Because of its superior efficiency and a remarkable ability to ride through serious radio static, it soon displaced all other methods for radio telegraph reception. It was for these same reasons that it was selected as the basis of the calling system for power line telephone communication. The heterodyne method was of course retained for the application to supervisory control.

In the heterodyne system, the incoming high-frequency signal is combined with a frequency generated locally. In this application, it is customary to adjust the locally generated frequency to within about 1000 cycles of the incoming signal frequency. This difference of frequency gives rise to a third frequency equal to the difference between the two main frequencies. This third frequency is commonly called the beat fre-

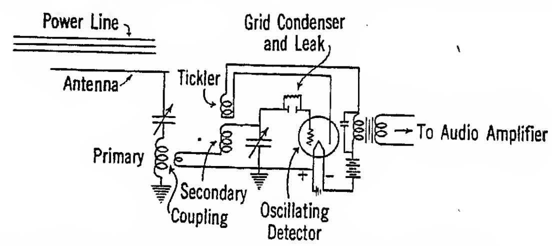

FIG. 3—SCHEMATIC OF RECEIVER USED FOR HIGH FREQUENCY CONTROL
The sector is kept in a state of continuous oscillation and heterodynes the incoming signal

quency. The second or locally generated frequency is in this case produced by maintaining the receiving detector in a state of continuous oscillation. The beat frequency of 1000 cycles is amplified by a two-step amplifier, the second step of which is adjustable and the output used to operate a polarized relay. This is accomplished by connecting two vacuum tubes in parallel as shown in Fig. 4 and supplying their plate circuit through a polarized relay having a suitable winding. The tubes are provided with a grid leak and condenser just as in the case of an ordinary radio detector. When the amplified 1000-cycle beat frequency is applied to the grids of the relay tubes, a negative charge is built upon the grid condenser in the usual way which gives the grids a large negative bias. This greatly reduces the plate current drawn through the winding of the polarized relay and allows the tension of a spring to close the relay contacts.

When the control frequency is put on the power line by the Kokomo transmitter, a beat is produced between the oscillating detector and the incoming frequency which, as described above, causes the relay contacts to close. When the flow of current from the Kokomo transmitter is interrupted, the relay contacts auto-

matically open. The calling dial of the sending transmitter is arranged to interrupt the flow of high-frequency current so as to produce a series of impulses. At each interruption, the contacts of the control relay close and thus give a corresponding series of impulses to the selector which it controls.

Selector

The type of selector used is that commonly employed in automatic telephone systems and now so widely used for supervisory control. It consists essentially of

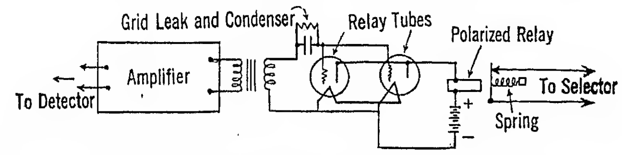

Fig. 4—Schematic Showing Method of Operating Polarized Relay

Two vacuum tubes are used in parallel to ensure ample mechanical pull at contacts

an electromagnet commonly called a motor magnet which drives a contact arm over a bank of contacts by means of a ratchet and pawl, as shown in Fig. 5. At each impulse of the radio or control relay, the motor magnet advances its contact arm one step. By a combination of fast and slow relays associated with the motor magnet, the circuit through the contact arm is held open until the proper code sequence is received. After the final pause in the series of code impulses, a slow relay drops out and completes the circuit to perform the desired operation if the correct code sequency has been received. The relay combination is such that during the advance of the selector contact arm a pause must be made at two predetermined points and there must be no interruption, in each group of impulses between the pauses. The total number of impulses must also add up to a predetermined total. Unless all of these conditions are fulfilled, the operating circuit cannot be closed. This interlocking combination is more elaborate than that commonly used in the calling system of standard power line telephone equipment.

The installation at Tipton is perhaps the oldest practical installation of supervisory control using high-frequency currents transmitted over a power line. In its initial stage it involved merely the application of a standard power line telephone system to the service of controlling oil service breakers. It was but a short step from this to the full system with answer-back applying all the well-known functions of modern supervisory control.

Answer-Back With Indicating Lamps

In order to provide for an answer-back signal, a small transmitting set was installed at Tipton and an additional receiver was added to the equipment at Kokomo. Controllers similar to those used for controlling oil circuit breakers replaced the automatic calling dial of the desk telephone set. These were mounted on a small panel and provided with the usual red and green indicating lamps. Automatic impulse senders were provided at Kokomo for sending the proper code impulses. The code sent out by the impulse sender was determined by the oil switch controller. Thus, to operate one of the Tipton breakers, the Kokomo operator was required to perform only the usual function of operating the controller of a standard oil circuit breaker. This started the automatic impulse sender which sent out a code of impulses corresponding to the particular controller operation performed.

When the code impulses were received at Tipton, the proper control circuits were completed and the desired breaker operation effected. At the completion of any circuit breaker operation a small transmitter was automatically started by means of a similar automatic impulse sender and a code was sent back to Kokomo corresponding to the breaker operation which had occurred. These impulses being received at Kokomo on selectors caused the proper indicating lamps to show on the Kokomo control board. The equipment was also arranged so that in case of doubt the operator could always check the position of the breakers.

Improvements in Mechanical Design

The mechanical arrangement and form of mounting used in the Tipton installation has been changed in later designs. The receiving equipment, instead of being built as a number of independent units and mounted on a table, has been changed to the arrangement shown in

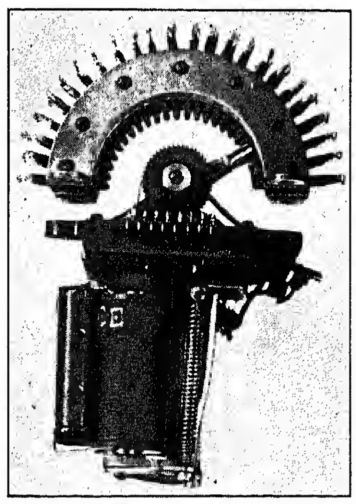

Fig. 5—View of Selector Showing Motor Magnet and Bank of Contacts

Fig. 6A-6B. The equipment is all mounted on panels which are accessible front and rear. The unit construction is still retained. The top panel carries the entire high-frequency equipment. A second panel carries all vacuum tubes and associated apparatus. The third panel carries the rectifier supplying the plate current to the vacuum tube system and the lower panel carries all relay and selective equipment together with the terminal board.

For work over short stretches of power line or over

sections of badly exposed telephone line, a small unit has been developed. This is a complete transmitter and receiver and also carries with it sufficient selective equipment for some simple applications. The unit is

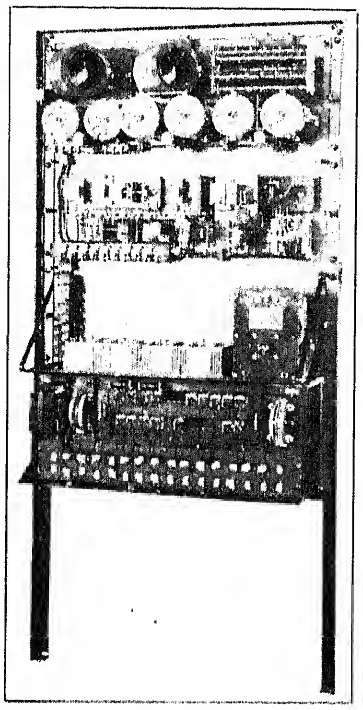

FIG. 6A—FRONT AND REAR VIEW OF PANEL TYPE RECEIVER SHOWING SELECTOR AND TERMINAL BOARD

adapted to either telephone service of supervisory control. The transmitter tubes are shown at the top. A master oscillator and four 7½-watt tubes are mounted so that they may be tied all four in parallel as oscillators for control work, or two may be used as oscillators and two for modulators for telephone service. The lower three tubes constitute the receiver. The unit is supplied with 500 volts of direct current from a dynamotor running on current furnished by a 24-volt storage battery.

The high-frequency system is well adapted for control using high voltage power conductors as a circuit. The system has also been applied to the control of series street lights fed from pole type regulating transformers. It is not well adapted to this class of service because of the bulk of the receiving equipment which must be hung on a pole and more or less exposed to the weather. It is not suitable to the control of multiple street lights This is again owing to the bulk and cost of the receiving equipment and to the fact that frequencies of the order of 50,000 cycles do not readily pass through transformers. The system is thus limited to service on high-tension lines.

MEDIUM-FREQUENCY SYSTEM

As early as 1901, Mr. Rhodes of the New York Edison Co. proposed to turn multiple street lights on and off by superimposing a 500-cycle control current on the power circuits. The early work did not show much promise and the project was dropped for some years. About four years ago the project was reopened and promising results obtained from preliminary work on the overhead system at Yonkers, New York. Subsequent development was carried out on the underground system of the Fordham substation of the New York Edison Co.

While the system was developed primarily for the control of multiple street lights, it has been found applicable to a wide variety of control problems. It is being applied to the control of street lights both series and multiple and to supervisory control of all kinds. Its simplicity is one of its principal points of merit. In addition, its receiving unit is very small in bulk and quite inexpensive. These features were essential to its success in the field of street light control.

The moderate-frequency system may possibly be best understood by discussing its application to street light control. Fig. 7 is a schematic diagram of a substation showing the method of energizing a single feeder. Feeders may be energized one at a time as in the schematic diagram, or in groups, or the entire bus may be energized according to the method of operation preferred. The control frequency is produced by the generator G. This is a rotating machine of a standard type, driven by a two-speed induction motor whose synchronous speeds are 1200 and 1800 rev. per min.

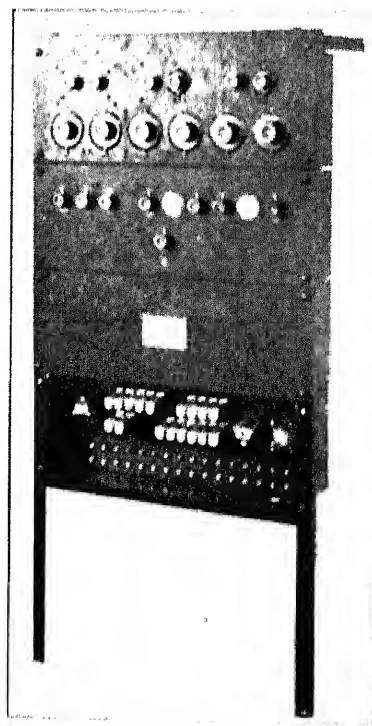

FIG. 6B—FRONT AND REAR VIEW OF PANEL TYPE RECEIVER SHOWING SELECTOR AND TERMINAL BOARD

This gives control frequencies of 440 and 660 cycles at synchronism. The motor is especially designed for low slip which is approximately 1½ per cent. Condensers of the oil-filled type similar to those regularly used for power factor correction are employed to couple the

generator to the line. Inductance coils are provided to tune the circuit as a whole. The power circuit presents a low impedance when viewed from the generator terminals. Hence a coupling transformer of suitable ratio is interposed between the generator and the tuned circuit to enable the generator to deliver its full output into the power system.

Method of Energizing Feeder

When energizing a single feeder, it is preferable to connect on to the feeder just beyond the feeder regulator and reactor, as indicated in Fig. 7. This will be apparent

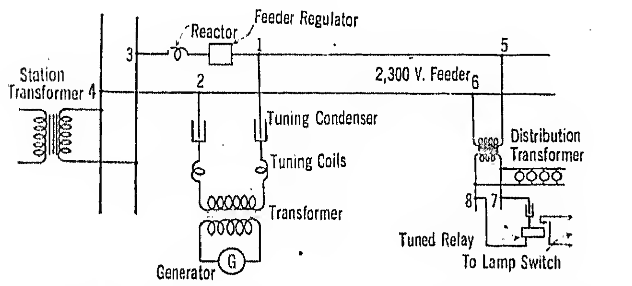

Fig. 7—Schematic Diagram Showing Method of Energizing Feeder for Medium Frequency Control

when it is observed that current delivered by the generator through the tuned circuit to the feeder has two paths in which to flow. It may flow out along the feeder through the numerous distributing transformers and it may also flow back into the station bus and through the large station transformers. If the generator is connected beyond the reactor and feeder regulator,

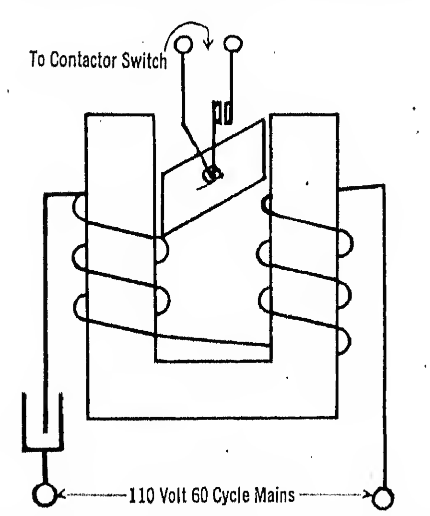

Fig. 8—Schematic Diagram of Resonant Relay

the impedance of these two elements is interposed in the path of the current flowing back through the station bus and less generator current is required to energize the feeder.

The control currents flow along the conductor just as though the power currents were not present. Sufficient current is fed into the system to establish a control frequency potential of approximately 100 volts at the outgoing terminals of the feeder. This control frequency potential acts throughout the whole length of the feeder in the same manner as the power frequency but it is quite independent of it. The various distribution transformers supplied by the feeder, step this control voltage down in the same ratio as they do the power voltages. Thus, with 100 volts of control frequency on the high side of a 2200-volt distribution transformer, five volts are delivered on the 110-volt side. It is this voltage which is available for the operation of the control relays.

At any point on the system where control is desired, a control relay is located as indicated in Fig. 7 and connected to the 110-volt side of a distribution transformer. It consists of a simple U-shaped magnet acting on a balanced armature as shown more clearly in schematic diagram, Fig. 8. A contact is mounted on the armature shaft and arranged to close when the relay is energized. A condenser is placed in series with the relay winding. The inductance of the winding is designed so that the inductive reactance of the relay is

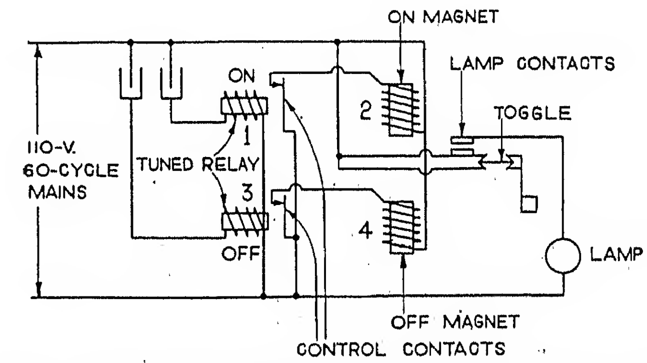

Fig. 9—Schematic Diagram of Street Light Control Unit Using Resonant Relays

exactly equal to the capacity reactance of the condenser at the frequency the relay is intended to operate on. The total reactance of the relay circuit including its condenser is therefore zero, and the control current passing through the relay is governed by Ohm's law, thus:

$$I = \frac{E}{R}$$

where E is the value of the control voltage impressed across the relay circuit, R is the effective resistance of the relay circuit, and I is the current flowing through the relay winding. When a circuit is adjusted so that its reactance is zero, it is said to be in tune or in resonance for this particular frequency.

Application to Street Light Control

In its application to street light control, it is clear that the lower the effective resistance of the relay circuit, the more energy will be available for its operation. This is owing to the low impedance of the supply circuits; the principal difficulty encountered in the

development of the relay was in keeping its losses sufficiently low. By careful selection of materials and proper proportioning of the magnetic circuit, these losses were cut well under the values necessary for commercial operation. It was the successful development of these low loss relays which made it possible to draw sufficient energy from the power system to operate a pair of contacts by the direct magnetic pull of the control current itself.

It will be apparent from the foregoing that when the feeder is excited by the control generator, all relays tuned to the control frequency will close their contacts.

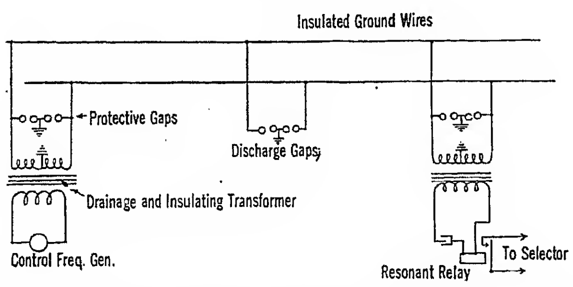

FIG. 10—SERIES STREET LIGHTS CONTROLLED BY MEDIUM FREQUENCY SYSTEM

By interrupting the flow of current from the control generator, the contacts of the resonant relays can be made to follow. Thus code impulses from the control frequency generator are reproduced by the contacts of the resonant relays. The system may therefore be used for control purposes of any kind.

In applying the system to street light control, two control frequencies are employed, one for turning the lights on and one for turning them off. Selection by using different frequencies is preferred in this case because of its simplicity. This requires two relays at each control point, one resonant to each control frequency. The contacts of the resonant relays are not required to carry the lamp current, but merely to throw a toggle switch which is provided with heavier contacts to carry the lamp current. Fig. 9 shows a schematic diagram of the two resonant relays and toggle switch as used in street light control. These elements are assembled in a weather proof case. The whole control unit is small enough to permit its being installed on the base of most ornamental street light posts.

In its application to the control of series street lights, the control unit governs the position of an oil switch in the primary side of a pole type regulating transformer as in Fig. 10. In this case, the feeder potential is usually 2300 volts and a potential transformer is necessary to supply 110 volts to the control unit. This transformer furnishes power frequency energy to operate the oil switch and control frequency energy to operate the resonant relays.

APPLICATION TO SUPERVISORY CONTROL

Supervisory control by means of moderate-frequency currents and resonant relays has recently been applied to a rather new problem. This is to provide for the control of numerous sectionalizing switches and some oil circuit breakers on a long 110-kv. line. The circuit over which the control system operates is rather novel. This circuit is obtained by insulating the ground wires ordinarily provided on a long high-tension line. The protective feature of the ground wires is not sacrificed appreciably owing to the installation of spark gaps at frequent intervals which provide a discharge path to ground. The sectionalizing switches to be controlled are installed at 15-mile intervals. At each point where a sectionalizing switch is located, a drainage transformer is provided with its middle point grounded in addition to the spark-gaps.

The control frequency is produced by a ½-kw. generator. This is connected to the line by a step-up insulating and drainage transformer. The generator voltage is 100 volts and the transformer is provided with taps to permit the use of line voltages of 300 to 500 volts.

The current supplied by the control generator is controlled by a standard system of supervisory control. The output of the generator is thus broken up into impulses and these impulses are received by resonant relays at the points where switches are to be controlled. The line voltage of 500 volts is stepped down to 10 volts by the insulating drainage transformer at each sectionalizing switch. This voltage is used to operate the resonant relays. The contacts of the resonant relays

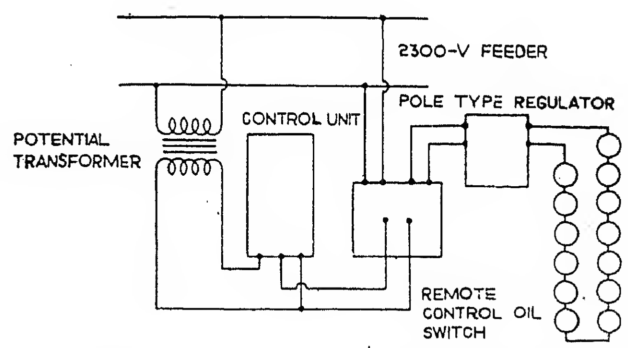

FIG. 11—SCHEMATIC DIAGRAM SHOWING SYSTEM OF MEDIUM FREQUENCY CONTROL USING CIRCUIT CONSISTING OF INSULATED GROUND WIRES

are connected in a circuit to repeat the impulses rereceived from the control generator into the selector system.

The selector system employs a combination of fast and slow relays together with associated motor magnets and contact banks as ordinarily used in automatic telephony and now adopted as standard practise for supervisory control. The complete supervisory system and resonant control relays are mounted on a switchboard section one panel wide. The type of line construction and the location of the spark-gaps and drainage transformers is shown in Fig. 11.

This application of medium-frequency alternating currents to the control of sectionalizing switches is likely to find wide application on long transmission lines where conditions will not justify a double-circuit line. By this means it is expected to reduce very greatly the interruptions to service arising from the use of a single-circuit line. The system may also have important applications on double-circuit lines and assist materially in the solution of control problems of all kinds.

Discussion

Chester Lichtenberg: One thing that is disturbing to the designers, as well as the operators, is the high cost of the equipment required for carrier-current supervisory control. At present the cost of wires is large; however, the terminal apparatus required for radio supervisory equipment is also large. It is therefore necessary to make a quite careful analysis of the situation before a reasonable conclusion can be drawn as to whether or not it is cheaper to use supervisory equipment employing wires or supervisory equipment using carrier current. From some studies which we have made, the wires seem more economical for distances up to about 25 mi., beyond that distance however, the carrier-current design becomes feasible.

The ambition of radio engineers seems to be to put supervisory equipment on high-tension transmission system. This is a splendid idea. It should be recollected however, that the supervisory equipment is most essential during times of stress, and such times will almost always coincide with high-tension transmission-circuit interruptions. Following this idea further, it is gratifying to note that the Alabama Power Company instead of using its high-tension transmission system, uses insulated ground wires. This follows in general the practise of the Chicago, South Shore, and South Bend Railway Company which uses a single wire for the control and indication of eight automatic substations.

L. H. Junken: (communicated after adjournment) A system of street-light control using high frequencies superimposed upon the distribution feeders has been developed by the General Electric Company in its general development of high-frequency control. This system uses a vacuum-tube oscillator for the generation of high-frequency power. This oscillator has an output of approximately 100 watts and is coupled to the distribution feeders on the line side of voltage regulators at the substation. The oscillator is built in the form of a switchboard panel and is approximately 33 in. wide, 76 in. high and 15 in. deep. The coupling capacitors used are small due to the small amount of control energy required and to the high frequency used which is about 40 kilocycles. The coupling capacitors are permanently installed on each feeder over which control is to be sent. The oscillator can then be switched from feeder to feeder on the low side of the coupling capacitors by means of low-voltage switching equipment. Since the frequency is high, the possibility of telephone interference is avoided and the presence of voltage regulators between the oscillator and the station bus prevents any appreciable amount of energy from flowing toward the bus and insures a maximum amount of energy flowing toward the feeder. This is a very economical arrangement, because it uses very small amounts of control energy.

The receivers are located along the feeders where pole-type constant-current transformers are to be controlled. The receivers are coupled to the feeder through small coupling capacitors which can be mounted on the crossarm in a way similar to that used for mounting lightning arresters. The receivers use a single vacuum tube for the detection of the high-frequency control current. This tube is operated at reduced rating and has a life of approximately one year. All of the power for the filament, grid, and plate potentials of the vacuum tube is taken from the secondary lines, no batteries or rectifier being required. The whole receiver is enclosed in a weather-proof sheet-steel box arranged for mounting on a pole. The receiving tube operates a d-c. relay in its plate circuit and this relay in turn operates a time-selector relay which controls the position of the switch in the primary of the constant-current transformer. The time-selector relay is so arranged that it closes the lighting circuit on a short impulse of control energy and opens the circuit on a longer impulse of control energy. The receivers are built to receive a suitable band of frequencies and require no tuning or other adjustments after their installation.

This system of control has been installed in service for street lighting in Schenectady and Rochester, N. Y., also Bayonne, N. J., for about two years and has given very satisfactory performance.

A. H. Kehoe: (communicated after adjournment) While the author mentions the control of multiple street lighting by high-frequency relays, the section of the paper covering applications of street-lighting control deals primarily with series lighting circuits. This is probably due to the fact that the multiple type of street lamp has not been extensively used in the past except in a few large cities. As there are economical advantages to be gained by using this type, provided a satisfactory method of control exists, it should be emphasized that the principal disadvantage of the multiple type of lighting in the past has been the difficulty of control. In the future, comparisons of the series vs. multiple systems for street-lighting applications should take this development into consideration, as it extends the field where multiple street lighting will prove to be the more economical of the two types of system.

H. M. Trueblood: (communicated after adjournment) Mr. Boddie's paper and other recent ones along similar lines serve to call our attention to the extent of the range of application of the carrier-frequency art. It was only about ten years ago when carrier-frequency telephone and telegraph circuits first appeared in the Bell System. Since then we have seen, first, a rapid development of carrier frequencies in commercial telephone and telegraph circuits; second, the use of carrier frequencies superposed on power transmission lines for the private communication services of power companies; and we now have the announcement of working applications of carrier frequencies for control purposes, a field which Mr. Boddie expects will be extensively widened.

In making note of these achievements we do so with the satisfaction any electrical engineer must feel in the furthering of the applications of electricity to the useful arts. We ought, however, to realize that the development and application of carrier frequencies along these three lines and others which may later appear, need to be carried out with proper regard to the possibilities of interference. In the development of commercial carrier-frequency telephone and telegraph circuits, where different systems are carried on the same pole line, engineers of the Bell Telephone System have been made fully aware of the difficulties of the interference problem, which appears here as a cross-induction problem more formidable than at voice frequencies. Methods which have been used to deal with it have included special attention to circuit balance, the suppression of the carrier wave itself, the use of a single side band, the selection of appropriate power levels, and a system of frequency allocations within the frequency range employed. No other methods than these appear to be open to us for dealing with the problem of induction in commercial communication circuits from carrier-frequency circuits as applied for control or communication purposes in connection with power lines, and the most fundamental of these methods at present is undoubtedly frequency separation. In fact, unless carrier-frequency circuits for communication or control purposes in connection with power-

circuit operation can be made to approach commercial communication circuits as regards balance and energy levels, I know of no means of avoiding interference in situations of close exposure other than frequency separation.

There is no serious situation at present as regards interference in commercial carrier-frequency communication channels from power lines, or any of the carrier-frequency applications used in connection with power-system operation, so far as I know. I believe that those of us who are working in carrier-frequency development in its various aspects should see that this fortunate condition continues. It is of interest in this connection to refer to the work of one of the project committees organized under the Joint Development and Research Subcommittee of the N. E. L. A. and Bell Telephone System which has been charged with, and is actively pursuing, a study of the problem of interference in carrier-frequency channels.

C. A. Boddie: I fully agree with Mr. Lichtenberg when he states that the application of high-frequency currents for control purposes is at present limited considerably by the high cost of the equipment. It is only on relatively long distances that there is a sufficient saving to justify the use of high-frequency currents so far as first cost is concerned. A good deal of work is being done in an effort to reduce these costs and it is hoped that a considerable improvement can be effected. But it is not the matter of first cost alone which is the chief consideration and stimulus to the use of high-frequency currents. It is rather the need of a mechanically more sturdy and more stable circuit than is attainable with telephone-line construction. It is this mechanical strength which can withstand sleet and storm and flood conditions inherent in power-line construction that offers the chief inducement to the use of high frequencies on such a line for communication and control.

The type of control described by Mr. Junken using relatively high frequencies generated by vacuum tubes is referred to in the paper. This type as stated is not suited to the control of multiple street lights, because such high frequencies will not pass through transformers and because of the size and cost of the individual receiving devices, each of which requires a vacuum tube and accessories. The system has a legitimate field of application for the remote control of regulating transformers for series lighting, since for this application relatively few receiving devices are required and the size and cost per unit is not a serious objection. The control currents are not required to pass through transformers as in the case of multiple lighting, but are taken off the high-voltage feeder by means of special coupling condensers.

I am glad Mr. Kehoe has emphasized the fact that the development of the system of control by the use of medium frequencies puts a new complexion on the problem of multiple vs. series street lighting. As he says the principal obstacle to the use of the multiple system has been the difficulty of control. In large cities the multiple system of distribution reaches everywhere. To supply street lights by the series system means a system within a system; that is, "duplication." The economic advantages of the multiple system which is universal for everything except street lighting may now be secured. The medium-frequency system of control was developed with special reference to the problem of controlling multiple street lights. Although as brought out in the paper it can be applied to the control of series lighting, its principal field of application is to multiple lighting. Perhaps this was not brought out in the paper as clearly as it should be.

With reference to Mr. Trueblood's discussion on the subject of interference, I might state that so far as street light control is concerned he will have little to fear. The development has not overlooked the question of interference with existing telephone lines. In the first place, the system is worked out so that the control frequency is applied to the line only twice a day and this is only for a period of several seconds. One of these operating periods comes at a time when interference if there should be any, would be of little consequence. In the second place, the control currents are confined entirely to the metallic conductors of the power system and are not permitted to return by way of ground. In the several installations which have been made there is no known interference with the telephone system, even that in the substation itself being immune.

Electromagnetic Waves Guided by Parallel Wires
With Particular Reference to the Effect of the Earth

BY S. A. LEVIN*

Associate, A. I. E. E.

Synopsis.—*A theory of the propagation of electromagnetic waves guided by a system of parallel wires is developed with particular reference to the effect of the earth, and is simplified so that it is identical in form with the elementary theory.*

Important general properties of a system of parallel conductors and their application to problems of propagation in power or communication circuits, or in a system of both types of circuits, derived by Professor Pleijel from the elementary theory, are mentioned together with several remarks of practical importance. The simplified theory leads to the same conclusions and, consequently, to the same applications.

The simplified theory gives promise of successful application to such problems of propagation in transmission systems which heretofore as a rule have not been formulated with sufficient precision.

INTRODUCTION

FOR the propagation of electromagnetic waves along any number of parallel wires of any configuration, mainly the elementary theory[1,2,3] has been employed†. Usually the earth is considered as very remote or as a perfect conductor. Rigorous theories have been developed in special cases for conductors in free space, as well as with proper regard to the influence of the earth. Earlier literature is found in reference 4; some recent work is mentioned in references 5 to 17, inclusive. A theory of propagation on a system of parallel wires, with particular reference to the effect of the earth, is developed in the theoretical part of this paper. To make this theory practically applicable, certain assumptions are made in the discussion. The simplified theory is identical in form with the elementary theory.

In a paper based upon the elementary theory Professor Pleijel[18] has derived general properties of a system of parallel wires and pointed out their application to several problems connected with the propagation of electromagnetic waves along power or communication circuits, or systems of both. The section of the present paper dealing with applications of the theory shows that these properties and their applications follow also from the simplified theory mentioned above and, in addition, contains remarks of practical interest.

It is believed that the simplified theory will permit application to many of those problems regarding electromagnetic wave propagation in transmission systems which previously were often not formulated with a sufficient degree of accuracy.

THEORY

Consider v wires of circular cross-section parallel to the z-axis, (see Fig. 1). Let the x z-plane separate the two media A, the air, and B, the earth. The conductors may be located in one or both of these media. Some may be of copper, some of iron, or any other material. All the conductors in the earth must be insulated. In the air, some or all of them may be covered with insulation. Some conductors may be arranged so as to correspond to a cable, but some of the following considerations do not strictly apply to such an arrangement. The conductors, the media A and B, and the

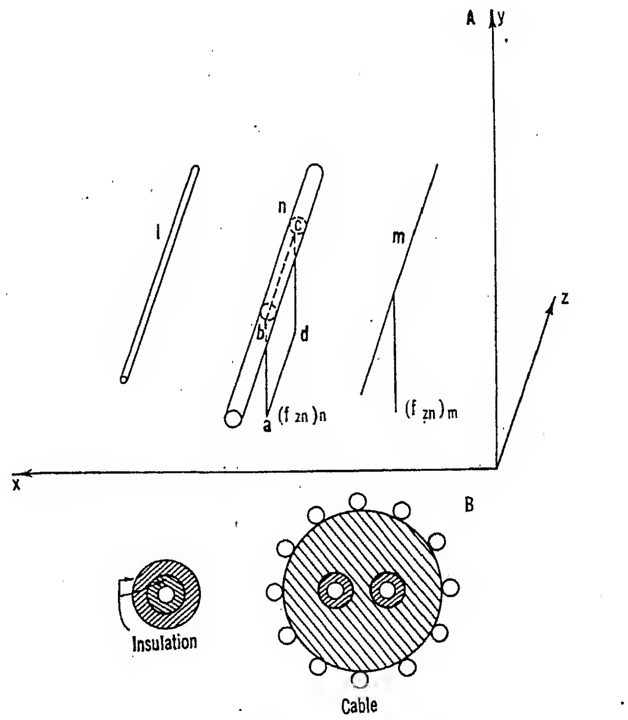

FIG. 1

insulating materials are supposed to be homogeneous and isotropic.

The separations between the conductors, and their distances from the surface of the earth, are supposed to be so large compared to the radii of the wires that the electromagnetic field inside each wire is symmetrical about the axis of the wire. The insulation of the wires is supposed to be so thin that it can be neglected. The fundamental assumption is that at a given frequency f

†See reference 21. This paper, however, was not known to the author when the present theory was developed.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 21-24, 1927.

the electromagnetic state* of the system can be represented, except at the ends, by a number of traveling waves. Only one of them with the propagation constant Γ will be considered, unless otherwise specified. The components of the corresponding electric and magnetic field vectors, F and H, respectively, are the real parts of the complex expressions, obtained by multiplying

$$F_x(x, y),\ F_y(x, y),\ F_z(x, y),\ H_x(x, y),\ H_y(x, y),\ H_z(x, y)$$

by the exponential factor $e^{-\Gamma z + j\omega t}$ where t is the time, $\omega = 2\pi f$ and $j = \sqrt{-1}$. The factors F_x, etc., are represented by different analytical expressions inside each wire, in the air, and in the earth. They satisfy the boundary conditions at the surfaces of the wires and at the surface of the earth.

Regarding the justification of the assumption of a field with the components

$$F_x(x, y)\, e^{-\Gamma z + j\omega t} \ . \ . \ . \qquad \textbf{(A)}$$

the following may be noted: Considering first the simple case of a single conductor of circular cross-section in free space, it has been shown by Sommerfeld[22] and Hondros[23] (see also references 24, 25, and 26 for other important contributions) that there are several fields each of the form (**A**) which satisfy the physical requirements; *i. e.*, Maxwell's equations and the conditions at the boundary and at infinity. Some of these fields are rejected for physical reasons. The remaining fields may be termed physical fields. Only experiment can decide if one or several of the physical fields actually can exist since the physical requirements do not determine the field uniquely. Experiment shows the observed field is equal to one of the physical fields, "the main wave." Thus, at least for the present purpose, it is unimportant whether or not there can exist the remaining physical fields, "the secondary waves," or any other field satisfying the physical requirements but not included among the main and secondary waves found by Sommerfeld and Hondros. Hondros has shown that the secondary waves are so strongly damped that they cannot be detected even if they exist. Reverting to the general case of a system of parallel cylindrical conductors, it may be expected that there are several fields, each of the form (**A**), satisfying the physical requirements, and that some of these fields are physical fields. Experiment may be expected to show that the observed field is equal to a field which is the resultant of certain of the physical fields, "the main waves." It may not be important to attempt a proof of these expectations if a number of fields are found which approximately satisfy the physical requirements and adequately account for the phenomena observed.

The z-component of the electric current in the wire n equals $\int \gamma_n F_z\, d s$ multiplied by $e^{-\Gamma z + j\omega t}$.

*Due to sinusoidal electromotive forces, of the frequency f, at the conductor terminals when the steady state is attained.

Let

$$\int \gamma_n F_z\, d s = I_n \qquad \textbf{(1)}$$

Hereafter the exponential factor $e^{-\Gamma z + j\omega t}$ will be omitted for the purpose of simplification. The conductivity of the wire is γ_n. The integral is extended over the cross-section of the wire, and its value, I_n, is independent of the location of the cross-section along the wire. The electromagnetic field everywhere outside the wires, *i. e.*, in the air and in the earth, would be the same as the field that would be produced there by currents I_n concentrated at the axes of the wires, if each wire were removed and replaced by the medium surrounding it. Consider an element of the concentrated current I_n. It produces an electromagnetic field that satisfies Maxwell's equations at all points in space and also satisfies the boundary conditions at the surface of the earth.[19] The same is true for the resultant field produced by any combination of elements. Let F_n, H_n be the vectors of the electromagnetic field produced outside the wires by all the elements of the current I_n alone. The components of these vectors are $F_{xn}(x, y)$, etc., multiplied by the exponential factor. The component H_{zn} can be neglected.† This permits of the definition of single-valued electric voltages and magnetic fluxes. Maxwell's equations are (elm. c. g. s. units),

$$\left.\begin{aligned} \operatorname{curl} H_n &= 4\pi\gamma F_n + K \frac{\partial F_n}{\partial t} \\ \operatorname{curl} F_n &= -\mu \frac{\partial H_n}{\partial t} \end{aligned}\right\} \qquad \textbf{(2)}$$

where the constants

γ = conductivity
K = dielectric constant
μ = permeability

have different values in the air and the earth. It follows from these equations and $H_{zn} = 0$ that

$$\left.\begin{aligned} F_{xn} &= -\frac{\Gamma}{4\pi\gamma + j\omega K} \frac{1}{\alpha} \frac{\partial F_{zn}}{\partial x} \\ F_{yn} &= -\frac{\Gamma}{4\pi\gamma + j\omega K} \frac{1}{\alpha} \frac{\partial F_{zn}}{\partial y} \\ H_{xn} &= -\frac{1}{\alpha} \frac{\partial F_{zn}}{\partial y} \\ H_{yn} &= \frac{1}{\alpha} \frac{\partial F_{zn}}{\partial x} \end{aligned}\right\} \qquad \textbf{(3)}$$

where

$$\frac{\partial^2 F_{zn}}{\partial x^2} + \frac{\partial^2 F_{zn}}{\partial y^2} = (4\pi j\omega\mu\gamma - \omega^2\mu K - \Gamma^2)\, F_{zn}$$

and $\qquad \textbf{(4)}$

†See, for instance, reference 21.

$$\frac{4 \pi j \omega \mu \gamma - \omega^2 \mu K - \Gamma^2}{4 \pi \gamma + j \omega K} \quad (5)$$

portional[19] to I_n.

$$F_{zn} = f_{zn}(x, y) I_n \quad (6)$$

satisfies equation (4) and consequently is represented by different expressions the earth, but it is continuous at the earth. For a given wire n the same ly for all waves. Thus, two waves on vith different values of Γ^2 give different ly because the Γ^2 values are different. ressed by saying that f_{zn} depends upon of f_{zn} at the x z-plane vertically below s n and m is $(f_{zn})_n$, and $(f_{zn})_m$, respec- l.

$$z_n I_n \quad (7)$$

internal impedance of the wire and is pendent of Γ^2.

flux per unit length through the loop 1, due to I_n, equals

$$\int_0^{h_n} - \frac{\mu}{\alpha} \frac{\partial f_{zn}}{\partial y} I_n \, dy = (\phi_n)_n I_n \quad (8)$$

is the distance from the surface of the plane, counted positive when the wire is lane. The flux per unit length through I_m is

$$\int_0^{h_n} - \frac{\mu}{\alpha} \frac{\partial f_{zm}}{\partial y} I_m \, dy = (\phi_m)_n I_m \quad (9)$$

$(\phi_m)_n$ depend upon Γ^2.

o ground of wire n equals,

$$\frac{\Gamma}{\pi \gamma + j \omega K} \frac{1}{\alpha} \sum_{n=1}^{v} \left(\frac{\partial f_{zn}}{\partial y} I_n \right) dy \quad (10)$$

plication of the second equation of (2)

$$V_n = Z_{nn} I_n + \sum_{m \neq n} Z_{mn} I_m \quad (11)$$

$$\left.\begin{aligned})_n + j \omega (\phi_n)_n &= R_{nn} + j \omega L_{nn} \\ + j \omega (\phi_m)_n &= R_{mn} + j \omega L_{mn} \end{aligned}\right\} \quad (12)$$

2) depend upon Γ^2. Z_{nn} is the self- vire n. Z_{mn} is the mutual impedance m and n when m carries the current. he self-resistance (inductance). R_{mn} utual resistance (inductance) when m nt. All impedances are per unit length.) are the vector voltage and current, they are understood in ordinary a-c. s from equation (11) that

$$-\frac{\partial (V_n)}{\partial z} = Z_{nn}(I_n) + \sum_{m \neq n} Z_{mn}(I_m) = \sum_{m=1}^{v} Z_{mn}(I_m) \quad (13)$$

Briefly, this is explained as follows. Note that all quantities in equation (11) are complex quantities. Put $V_n = V_{n1} + j V_{n2}$, etc. Multiply equation (11) by $e^{-\Gamma z + j\omega t}$, calculate the real parts of the expressions on both sides of the equality sign and put them equal to each other. The equation thus obtained will contain two expressions on the left side of the equality sign, each containing a factor one of which is the time-derivative of the other. A similar remark applies to the expression to the right of this sign. It is seen that the equation gives a relation between the instantaneous voltage and current values which are the real parts of $V_n e^{-\Gamma z + j\omega t}$, etc., so that the vector expression on the right in equation (13) equals the vector $\Gamma (V_n)$. Finally, the derivative with respect to z of the instantaneous voltage shows that the vector relation $\Gamma (V_n) = -\frac{\partial (V_n)}{\partial z}$ is true.

From the usual application of the fact that the divergence of the sum of the conduction and displacement current is equal to zero, it follows that

$$\Gamma I_n = 2 \pi r \left(\gamma + \frac{j \omega K}{4 \pi} \right) F'$$

where r is the radius of the conductor n and F' the component, normal to the surface of the conductor, of the total electric field immediately outside this surface. The total leakage current from the conductor per unit length is $2 \pi r \gamma F'$. The total electric charge on the conductor per unit length is $2 \pi r \frac{K}{4 \pi} F'$. The intersection between a plane z = constant, the surfaces of the conductors, and the surface of the earth consists of a number of circles and a straight line. The voltage on each circle is constant. If, as an approximation, the voltage on the line is assumed constant, it follows by comparison with familiar electrostatic methods* that

$$\Gamma I_n = \sum_{m=1}^{v} \beta_{mn} V_m$$

where $\beta_{mn} = \beta_{nm}$ and both are complex coefficients independent of Γ^2. Consequently

$$-\frac{\partial (I_n)}{\partial z} = \sum \beta_{mn} (V_m) \quad (14)$$

Equation (14) can also be written

$$-\frac{\partial (I_n)}{\partial z} = (A_{nn} + j \omega C_{nn})(V_n) +$$

*Neglecting[7], in the dielectric, ΓF_z in div. $F = 0$.

$$\sum_{m \neq n} (A_{mn} + j\,\omega\,C_{mn})\,[\,(V_n) - (V_m)\,] \qquad (15)$$

where the coefficients A and C are the leakages and capacities per unit length, respectively.

If

$$Z_{mn} = Z_{nm} \qquad (16)$$

then

$$\left.\begin{array}{l} R_{mn} = R_{nm} \\ L_{mn} = L_{nm} \end{array}\right\} \qquad (17)$$

Since

$$\beta_{mn} = \beta_{nm} \qquad (18)$$

thus

$$\left.\begin{array}{l} A_{mn} = A_{nm} \\ C_{mn} = C_{nm} \end{array}\right\} \qquad (19)$$

The general validity of equation (16) has not been investigated here.[15] In the following case the equation holds. In Fig. 1 let $n = 2$. The flux per unit length through the loop $a\,b\,c\,d\,a$ due to the current $I_1 = 1$ is

$$(\phi_1)_2 = \int_0^{h_2} -\frac{\mu}{\alpha}\frac{\partial f_{z1}}{\partial y}\,d\,y$$

The voltage to ground at wire 2 due to $I_1 = 1$ is

$$V = \int_{h_2}^{0} \frac{\Gamma}{4\,\pi\,\gamma + j\,\omega\,K}\,\frac{1}{\alpha}\,\frac{\partial f_{z1}}{\partial\,y}\,d\,y$$

Let $f_{z1}\,(h_2)$ represent the value of the function at the surface of wire 2. The second equation of (2) gives

$$f_{z1}\,(h_2) - (f_{z1})_2 = \frac{\Gamma^2}{(4\pi\,\gamma + j\,\omega K)\mu}\,(\phi_1)_2 - j\;\omega\;(\phi_1)_2$$

If $\Gamma = 0$, then

$$f_{z1}\,(h_2) = -\,Z_{12}$$

i. e., the z-component of the electric field at the wire 2 due to $I_1 = 1$ equals the negative value of the mutual impedance. The z-component of the electric field at the wire 1 due to $I_2 = 1$ equals

$$f_{z2}\,(h_1) = -\,Z_{21}$$

But[14] when $\Gamma = 0$

$$f_{z1}\,(h_2) = f_{z2}\,(h_1),$$

This relation is also true[20] when $\Gamma \neq 0$. Thus, when $\Gamma = 0$, equation (16) holds irrespective of the location of the wires.

It can easily be shown that all previous considerations can be extended to the case where the insulation of the wires has finite thickness and the space below the $x\,z$-plane is occupied by layers of different homogeneous and isotropic materials, provided no conductor is close to the surface separating two such layers. For instance, immediately below the $x\,z$-plane there may be a layer of water followed by a layer of earth, and so forth.

Discussion of Theory

Consider equations (13) and (14) or (15) for a given wire n. Write down all equations (13), one for each Γ, also all equations (14). If the corresponding coefficients in equations (13) and the corresponding coefficients in equations (14) were all equal, the addition of equations (13) and the addition of equations (14) show that these equations apply to the total values of the voltages and currents. The coefficients in (12) are, however, unequal for all waves with unequal values of Γ^2. The equations do not apply strictly to the total values of the voltages and currents, except in the case when only two waves exist with the propagation constants Γ and $-\,\Gamma$. For most practical purposes it will be necessary to make an approximation.

The approximation mentioned consists in the use of equations (13), (14), and (15) in which the vectors denote total values, and equation (16), it being understood that it is desirable to determine experimentally the limitations of such a procedure. The equations are then identical in form with the equations of the elementary theory. The present theory represents an advance, at least in so far as the effect of the finite conductivity of the earth manifests itself in the coefficients. The theory gives a physical picture of the phenomena occuring in the conductors and in space.

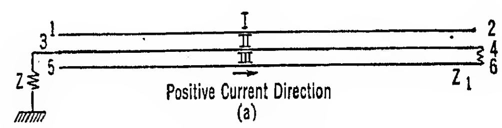

Fig. 2A

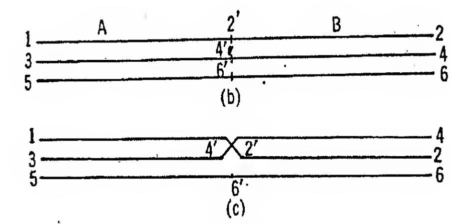

Fig. 2B, 2C

It also points out the approximations involved in the elementary theory.

Some Applications of the Theory

Let 1, 2, 3, 4, etc., denote the ends of wires, I, II, III, etc., see Fig. 2A. The total vector voltage to ground and the current at 1 will be denoted by v_1 and i_1, respectively, and so on. It follows[18] from equations (13) and (15) that

$$\left.\begin{array}{rl} v_1 &= b_{11}\,i_1 + b_{12}\,i_2 + b_{13}\,i_3 + b_{14}\,i_4 + \dots \\ -\,v_2 &= b_{21}\,i_1 + b_{22}\,i_2 + b_{23}\,i_3 + b_{24}\,i_4 + \dots \\ v_3 &= b_{31}\,i_1 + b_{32}\,i_2 + b_{33}\,i_3 + b_{34}\,i_4 + \dots \\ -\,v_4 &= b_{41}\,i_1 + b_{42}\,i_2 + b_{43}\,i_3 + b_{44}\,i_4 + \dots \end{array}\right\} \qquad (20)$$

etc.

where the coefficients $b_{nm} = b_{mn}$ are composed of the coefficients in equations (13) and (15) in a complicated way. Since the line is uniform throughout its length, it follows[18] that

$$\left.\begin{array}{ll} b_{11} = b_{22} & b_{31} = b_{42} \\ b_{13} = b_{24} & b_{32} = b_{41} \quad \text{etc.} \\ b_{14} = b_{23} & b_{33} = b_{44} \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \end{array}\right\} \quad (21)$$

Let A and B be two sections, see Fig. 2B, such that equations (**20**) and (**21**) apply to each of them but with constants b differing on account of changes in the earth conductivity, the geometry of the system, and so forth. The changes in the geometry may be due to transpositions, see Fig. 2C, different spacings, different distances from the ground, etc. There will be a relation (**20**) between the quantities at 1, 3, 5 and at 2′, 4′, 6′. A similar relation will hold between the quantities at 2′, 4′, 6′ and at 2, 4, 6. Eliminating the quantities at 2′, 4′, 6′ gives equation (**20**) where $b_{nm} = b_{mn}$, but equation (**21**) no longer holds. If several sections are added in this way, the result is always equation (**20**) with $b_{nm} = b_{mn}$.

Let A, Fig. 2D, be a system, composed of one or several sections. At one end of the system are impedances Z_1 and Z_2 (*e. g.*, loading coils); they may also have a mutual impedance Z_{12} (*e. g.*, booster transformer). One wire may be grounded through an impedance Z (*e. g.*, ground wire). Between the quantities at 2″, 4″, 6″ and at 2, 4, 6, a relation (**20**) holds, which together with

$$\left.\begin{array}{l} v_2' = v_2'' \\ i_2' = i_2'' + \dfrac{v_2'}{Z} \\ i_4' = i_4'' \text{ and } i_6' = i_6'' \\ v_4' = v_4'' + Z_1 i_4' + Z_{12} i_6' \\ v_6' = v_6'' + Z_2 i_6' + Z_{12} i_4' \end{array}\right\}$$

permits the elimination of the quantities at 2″, 4″, 6″. The result is equation (**20**) between the quantities at 2′, 4′, 6′ and at 2, 4, 6 where now some of the coefficients b will contain Z_1, Z_2, Z, etc., but still remain such that $b_{mn} = b_{nm}$. If the system A, including its equipment of terminal impedances Z_1, Z_2, Z, etc., is connected to another system B, see Fig. 2D, the result is still equation (**20**).

If a transformer is connected as shown in Fig. 2E, it is easy to show that there is not a sufficient number of equations to permit the elimination of the quantities at 2′, 4′. Equation (**20**) does not apply in such a case.

If necessary, divide a system into sections so that equation (**20**) applies to each section. The terminal conditions of such a section will now be considered. The wires may be interconnected at the ends, ground connections may also be used. For instance, the point 3, Fig. 2A may be grounded through an impedance Z. Then

$$v_3 = -\, i_3\,(Z + R)$$

where R is the ground resistance of the grounding device. This resistance is included to correct, at least approximately, the conditions at the ends of the system where the considerations of the paper do not strictly apply. This resistance R also should be included in Z in Fig. 2D. If the points 4 and 6, see Fig. 2A, are connected by an impedance Z_1, then

$$i_4 = -\, i_6,\; i_4 Z_1 = v_4 - v_6$$

and so forth. In this connection the following may be noted, see Fig. 2A. The wires I, II, III, may continue to the right of the points 2, 4, 6. The system to the right is then the termination of wires I, II, III at these points.

It is possible to determine the coefficients b in equation (**20**) by experiment.[18] These equations are of fundamental importance and, together with their consequences, permit of important applications.[18] At first sight the great number of coefficients to be determined would seem to hinder applications, except when the number of wires is small. Fortunately this is not

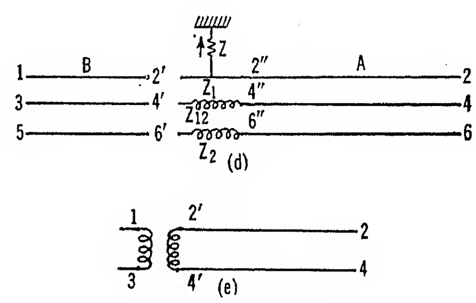

FIG. 2D, 2E

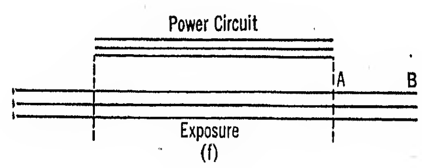

FIG. 2F

the case. It is possible, for instance, in a lead containing a large number of wires, to study the currents and the voltages to ground at the ends of one wire, or the currents and the voltages between two wires at the ends of a loop of these two wires, by measuring only a few coefficients. This has been shown in a few cases,[18] which correspond, for instance, to the propagation of voltage and current along a single telephone wire, or a loop of two wires, from the end A, see Fig. 2F, of an exposure between power and communication circuits to a point B, where the currents and the voltages may be of interest. There are also other cases when a study can be made by measuring relatively few coefficients, as can easily be shown by methods similar to those employed in the paper referred to.[18] Thus, for instance, the voltages and the currents induced in a single wire or a loop of two wires in a lead can be studied by comparatively few measurements.

In conclusion, some remarks will be made regarding

the application of equation (20) to problems of inductive coordination between power and communication circuits.

It is customary and useful to distinguish between uniphase and balanced currents and voltages on a power system and consider the induction on a telephone system due to them separately. It is seen that the coefficients b are applicable both to uniphase and balanced induction. Once the uniphase and balanced components are known in magnitude and phase at the ends, the inductive effects can be found by using the same coefficients b. It is not necessary to use separate coefficients for balanced and uniphase induction. This facilitates experimental work and analysis considerably.

The impedances of loading coils, booster transformers, etc., appear in the coefficients b, as seen above. The effect of the line proper can be determined, if all these devices are short-circuited. If the coefficients are then determined with these devices their influence can be found.

The coefficients have to be determined at different frequencies. At a given frequency they will, presumably, depend upon the current density when iron is present in the circuits.

It is possible to calculate the coefficients b for a simple system, assuming the earth to be a perfect conductor, or very remote. If the coefficients are measured the comparison between the measured and calculated coefficients gives an idea of the effect of the earth.

The irregularities in the geometry of the system, in the earth's conductivity, and so on, appear in the coefficients b, determined experimentally. This is of very great importance, particularly for the voltages between two neighbouring wires. If, as is often done, their voltages to ground are calculated by some method, even of great accuracy, then the difference between these two calculated voltages which are usually fairly large is not equal to the actual voltage between the wires, usually fairly small, since even small errors due to irregularities of the system in the voltages to ground give a large error in their difference.

Conclusions

A theory of propagation of electromagnetic waves guided by parallel wires with regard to the effect of the earth has been developed. The theory shows how the finite conductivity of the earth enters into the problem of propagation. It also gives an idea of the physical phenomena involved. The approximations necessary for the development of a simplified theory suitable for engineering applications have been pointed out. Some applications of the simplified theory to transmission systems for power and communication purposes, suggested by Professor Pleijel, have been indicated, together with remarks of practical interest.

Discussion

L. C. Peterson: (communicated after adjournment) In connection with some tests planned to determine the inductive coupling at the higher frequencies between different wires of a system of parallel wires, a theoretical study was made in June and July of 1926, based on a paper by Professor Pleijel entitled "Current and Voltage Relations in a System of Parallel Conductors" and given as reference No. 18 in Mr. Levin's paper. In his paper, Professor Pleijel gives a set of linear equations connecting the terminal currents and voltages of a multi-wire line. In the underlying transmission theory, the ground is assumed to have infinite conductivity. Mr. Levin states that he has demonstrated the validity of Pleijel's equations, as regards their form, when the finite conductivity of the ground is taken into account. Such a demonstration is quite unnecessary; indeed, the fact that the equations maintain the same form irrespective of any assumption regarding the ground conductivity, or any approximation introduced in the transmission theory, follows immediately from the general properties of an n-terminal network. The coefficients in Pleijel's equations (given as eq. (20) in Levin's paper) uniquely specify the system and hold for all possible terminal connections of the line wires. They offer, therefore, a means of determining the induction in systems of parallel conductors. In a limited number of cases, these coefficients may be calculated from the dimensions of the system. However, calculations being rather laborious, it is advantageous to resort to the experimental determinations of the coefficients.

In a system of n conductors, $n\ (2\,n + 1)$ independent coefficients will be necessary to define the system completely but if the system is electrically symmetrical around its midpoint, this number of independent coefficients is reduced to $n\ (n + 1)$. For instance, an unsymmetrical three-phase system is determined by $3\ (6 + 1) = 21$ coefficients and a symmetrical three-phase system by $3\ (3 + 1) = 12$ coefficients. It is obvious that in the general case the determination of $n\ (2\,n + 1)$ coefficients will be required and hence, $n\ (2\,n + 1)$ measurements.

Methods for experimental determination of the coefficients b in eq. (20) of Mr. Levin's paper have been worked out. It can readily be shown that all the coefficients are obtainable from open- and short-circuit impedance measurements on the individual wires or on combinations of these wires.

S. A. Levin: The validity of Pleijel's equations for any finite value of earth conductivity, eq. (20), can be shown as done in the paper of reference (18) provided eqs. (13) and (15) are demonstrated for finite conductivity. According to Mr. Peterson, the validity of Pleijel's equations for any finite value of earth conductivity follows from the theory of an n-terminal network. It seems to me that the application of this theory to a system of parallel conductors also requires that eqs. (13) and (15) are demonstrated for finite conductivity. This is the only demonstration attempted in my paper. I cannot see, therefore, that it contains any unnecessary demonstration whether Pleijel's equations are obtained one way or the other.

Present Status of the International Electrical Units*

BY E. C. CRITTENDEN†
Member, A. I. E. E.

Synopsis.—*This paper summarizes the present legal standing and practical usage of the international electrical units, particularly as maintained in the United States. The international agreement reached in 1910 was provisional and requires some revision. Further investigations of the international standards, as well as of the absolute units, are urgently needed to put the system on a satisfactory basis for work of high precision.*

Legal authority to deal with electrical units has now been given the International Committee on Weights and Measures. This provides a permanent working organization through which international agreements can be reached and can be made effective throughout the world.

When the committee takes up the question of electrical units for formal international adoption, it will have to decide whether to maintain as nearly as is practicable the values accepted at present or to revise them so as to accord with the fundamental c. g. s. system. With regard to primary standards, it will have to choose between the mercury ohm and silver voltameter, on the one hand, as against direct determination of the units by methods based on mechanical dimensions.

The Bureau of Standards has under way several investigations planned to give a better technical basis for final decisions on these questions. It is desirable also that they be discussed by those interested in making precise and accurate electrical measurements in order that all the advantages and disadvantages of the changes proposed may be given adequate consideration.

Introduction

WHILE many systems of electrical units have been proposed, the leaders in electrical science and engineering since the time of Weber have almost invariably adhered to the principle that fundamental electrical measurements should be based on the mechanical effects of electricity, and thus be made concordant with measurements in other fields of science and engineering. The metric system has also been generally accepted as the basis for the electrical units.

Even though this general principle is accepted, there are many sets of alternatives between which a choice must be made. For example, one may start with the mechanical forces between electric charges at rest, or on the other hand, first consideration may be given to the magnetic effects which are of so much greater importance in connection with electric currents. In other words, the basis of the system of units may be either electrostatic or electromagnetic effects.

In fact, systems of both kinds are used, and each has special advantages for particular cases. The greater importance of electromagnetic relations in the practical use of electricity, and the facility with which precise measurements of electric current can be made by the use of magnetic effects, have combined to give the electromagnetic system a predominating position. It is nevertheless worth noting that developments of recent years, especially in high voltage work and in electronics, have made electrostatic effects more prominent than they formerly were. It has been established beyond reasonable doubt that all material is composed of constellations of electric charges. The numerical values of these elementary charges have been determined with precision. In numerous devices they already serve us, and the future importance of their direct uses no one can foretell. In this great and growing field of science and practise, essential values are naturally determined in absolute electrostatic units.

It would be beside the point to discuss here the various combinations of units which have been proposed for the purpose of simplifying the numerical relations between quantities and thus making computations easier. These proposed systems are treated at some length in Bureau of Standards Circular No. 60, "Electric Units and Standards,"[1] and Scientific Paper No. 292, "International System of Electric and Magnetic Units."[2] In brief, the view set forth in those publications is that in the "practical" electromagnetic system, as modified by the adoption of the present international units, there has been developed a set of units more generally satisfactory than any of the systems proposed on a theoretical basis. Consequently, it is concluded that there is no good reason to incur the confusion which would result from an attempt to change the units now ordinarily used.

During the last 10 years there has been no agitation for radical changes in the present system, and certainly no such proposals would now be received with favor. No one would seriously propose to do away with the ohm, the ampere, or any of the important units derived from them. It is, however, an open question whether the values of these units as now accepted should not be adjusted to make them accord more closely with the general system of measurements. Furthermore, we may well inquire whether the methods of determining these values have not reached such a stage of perfection that the old expedients for maintaining constancy of the units can be safely discarded. If any such changes of units or of fundamental standards are to be made,

*Approved by the Director of the Bureau of Standards, Department of Commerce.

†Physicist, Chief of Electrical Div., Bureau of Standards, Washington, D. C.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

1. For numbered references see bibliography.

they must, of course, be thoroughly considered in advance in order that the advantages and disadvantages resulting from the change may be fully weighed. The purpose of this paper is therefore to set forth the present status of the units and to ask for discussion of the changes which might logically be made if found expedient.

Legal Basis of the Units in the United States

The legal basis for the electrical units used in the United States is still the Act of July 12, 1894. This accepted the international ohm, ampere, volt, coulomb, farad, joule, watt, and henry, as adopted at the International Electrical Congress held at Chicago in 1893, and incorporated definitions paraphrasing without essential changes the resolutions adopted by that Congress. The definitions given in the Act for the ohm, ampere, and volt were as follows:

> 1. The unit of resistance shall be what is known as the international ohm, which is substantially equal to one thousand million units of resistance of the c. g. s. system of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14.4521 g. in mass, of a constant cross-sectional area, and of the length of 106.3 cm.
>
> 2. The unit of current shall be what is known as the international ampere, which is one-tenth of the unit of current of the c. g. s. system of electromagnetic units, and is the practical equivalent of the unvarying current, which, when passed through a solution of nitrate of silver in water in accordance with standard specifications, deposits silver at the rate of 0.001118 of a gram per second.
>
> 3. The unit of electromotive force shall be what is known as the international volt, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of an international ampere; and is practically equivalent to $\frac{1000}{1434}$ of the electromotive force between the poles or electrodes of the voltaic cell known as Clark's cell, at a temperature of 15 deg. cent., and prepared in the manner described in the standard specifications.

It will be seen that these definitions do not draw a sharp distinction between the basic c. g. s. units and those defined in terms of concrete standards. If taken literally, the law is inconsistent with regard to the relations between the two sets of units. The exact value of the ohm is to be that obtained from the mercury column, the absolute unit being mentioned merely as a substantial equivalent, while in the case of the ampere this condition is reversed.

Section 2 of the same act provided,

> That it shall be the duty of the National Academy of Sciences to prescribe and publish, as soon as possible after the passage of this Act, such specifications of detail as shall be necessary for the practical application of the definitions of the ampere and volt hereinbefore given, and such specifications shall be the standard specifications herein mentioned.

This section has become a dead letter, since it was necessary to depart from the National Academy specifications in order to obtain consistent results and to obtain international agreement. Except in this detail, however, it has been possible to follow the terms of the law literally and still to put into effect the international agreements which have been reached. The differences between the absolute and the accepted international unit of current have been negligible, and the terms in which the Clark cell were referred to were not such as to require its use, so that there has been no legal obstacle to the adoption of the Weston normal cell as a substitute for the Clark.

The Present Units

The values of the units now accepted for practical use throughout the world were established, in principle, by the International Conference on Electrical Units and Standards, held in London in 1908. This conference made a clear distinction, so far as definitions are concerned, between the absolute units and those which were called international. The Conference used the term "fundamental" for the units here called absolute, that is, those derived from the basic units of length, mass, and time. With reference to these units, the following resolution was adopted:

> The Conference agrees that as heretofore the magnitudes of the fundamental electrical units shall be determined on the electromagnetic system of measurement with reference to the centimetre as the unit of length, the gramme as the unit of mass, and the second as the unit of time.
>
> These fundamental units are:
>
> 1. The *Ohm*, the unit of electric resistance which has the value of 1,000,000,000 (10^9) in terms of the centimetre and second,
>
> 2. The *Ampere*, the unit of electric current, which has the value of one-tenth (0.1) in terms of the centimetre, gramme, and second,
>
> 3. The *Volt*, the unit of electromotive force which has the value of 100,000,000 (10^8) in terms of the centimetre, gramme, and second,
>
> 4. The *Watt*, the unit of power which has the value of 10,000,000 in terms of the centimetre, the gramme, and the second.

As a system of units representing the above and sufficiently near to them to be adopted for the purpose of electrical measurements and as a basis for legislation, the conference recommended the adoption of the

international ohm, ampere, volt, and watt, defined as follows:

> The *International Ohm* is the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14.4521 grammes in mass, of a constant cross-sectional area and of a length of 106.300 centimetres. (The procedure to be followed in setting up mercury ohms was prescribed in detail in specifications attached to the resolutions.)
>
> The *International Ampere* is the unvarying electric current which, when passed through a solution of nitrate of silver in water, in accordance with the Specification II attached to these Resolutions, deposits silver at the rate of 0.00111800 of a gramme per second.
>
> The *International Volt* is the electrical pressure which, when steadily applied to a conductor the resistance of which is one international ohm, will produce a current of one international ampere.
>
> The *International Watt* is the energy expended per second by an unvarying electric current of one international ampere under an electric pressure of one international volt.

It is perhaps worth noting that the units of mass and length included in these definitions occur in the description of the apparatus by which the units are to be established, and are not involved in the real definitions of the units themselves. That is, these dimensions could be stated in any other mechanical units desired without affecting the value of the electrical units; the latter are essentially defined in terms of the properties of mercury and of silver without any reference to systems of measurement. They therefore become independent, fundamental units which, joined with the centimeter and the second, constitute the basis of a complete system from which even mechanical units including the gram might be derived.

While these definitions were thus made in form quite independent of the absolute electrical units defined in terms of the centimeter, gram, and second, the intention of the conference was to make the units adopted represent very closely the value of the absolute units. In fact, one reason advanced for choosing the ampere, instead of the volt, as a fundamental unit was the possibility of direct determination of the absolute value of the ampere by several methods independently of any assumed value for the ohm or other electrical units.

The definition adopted for the ampere carried the value to six significant figures although it was recognized that the specifications for the voltameter were incomplete and therefore indefinite. An International Committee on Electrical Units and Standards was created to complete the work of the conference and to carry it on until another conference should be convened. Among other duties, this committee was to secure agreement on precise specifications for the voltameter and to establish a standard value for the electromotive force of the average Weston normal cell consistent with the international ohm and the ampere as defined by these specifications. The accomplishment of an important part of this task was made possible by the generous support of four American societies, the American Institute of Electrical Engineers, Association of Edison Illuminating Companies, Illuminating Engineering Society, and National Electric Light Association. These societies contributed funds to bring representatives of Great Britain, France, and Germany to America for joint experiments with the Bureau of Standards upon the silver voltameter and the standard cell. The Technical Committee thus created worked at Washington for nearly two months in 1910. It did not agree on formal specifications for the voltameter, but it did bring the experimental results with different types of voltameters nearly enough into accord so that the value of 1.0183 at 20 deg. cent. for the Weston normal (saturated) cell was established and accepted internationally.

Values of the Ohm

When the Technical Committee met in 1910, it had at hand wire standards calibrated in terms of the mercury ohms at the German Physikalisch-Technische Reichsanstalt and the British National Physical Laboratory. The two values for the ohm were found to differ by only one part in 100,000, and the mean value was accepted by the Technical Committee in the following resolution:

> The committee decides to choose, for the present and until there are other mercury ohms prepared, as the value of the international ohm, to be recommended to all countries for general use, the mean of the values of the units realized at the Physikalisch-Technische Reichsanstalt and at the National Physical Laboratory. Although the international ohm as defined by the London Conference has not yet been strictly realized, the committee believes that its value has been attained in two laboratories independently with a good degree of precision, and that future work is not likely to change it by more than two or three parts in 100,000.

It will be seen that this acceptance of a mean value to be called the International Ohm was really provisional. The International Committee never succeeded in completing the full and formal establishment of the unit, and no machinery was provided for the distribution and maintenance of a common unit. The work of the committee did, however, show that the resistance standards of the several national laboratories were already in fairly good agreement. Since the standards were thus reasonably concordant, in general each laboratory considered it best to maintain the continuity

of its own values rather than to make small changes in advance of a complete international acceptance of a precise value.

In fact, a mercury ohm determination completed at the Bureau of Standards a few years later[3] gave a value differing from the international ohm accepted in 1910 by 25 parts in a million. This was considered to be a check within the limits of certainty of the mercury ohm, and the values assigned to the Bureau's wire standards were not changed. Since 1915 no mercury ohm determinations have been made at the Bureau. The unit has been preserved by sets of wire standards whose relative values have been found to be very stable. The unit has been maintained on the assumption that the mean resistance of a group of 10 one-ohm manganin wire standards remains constant. The ten standards included in the reference group are, however, not always the same. Intercomparisons with a considerably larger group are made from time to time, and those standards which have apparently been most stable are chosen for the reference group which is the custodian of the unit until the next intercomparison is made. Since 1910, 17 different standards have thus at various times been included in the reference group.

Comparisons of the ohm as maintained in different countries have been made only irregularly, but the results have indicated that all the national laboratories have remained in satisfactory agreement. The differences found have seldom been greater than two parts in 100,000, which is about the limit of accuracy obtainable in the establishment of the international ohm.

In recent years an entirely unexpected complication has arisen which makes the old definition of the international ohm indefinite. This is the discovery that mercury is not a simple element but includes several isotopes. If completely separated, these would presumably differ in density by as much as 3 per cent, although they have the same resistivity on the basis of volume. This difficulty is not a serious one, however, since mercury from many sources as ordinarily produced has been shown to have the same density within a few parts in a million. At any rate, the difficulty can be met by specifying the density of the mercury to be used in the ohm tubes or by prescribing the cross-section instead of the mass of the mercury column.

Although the mercury ohm affords a means, however, of checking the value of the unit to a few parts in 100,000, determinations of the absolute value of the international ohm have shown that this unit differs by a considerable amount from the basic unit with which it was intended to be practically equivalent. Two very careful determinations have been made since 1910 by entirely different methods, one at the National Physical Laboratory,[4] with an apparatus of the Lorenz disk type, the other at the Reichsanstalt[5] by comparison of resistance standards with the calculated self-inductance of a coil. The two results agree within one part in 100,000. This close agreement must be considered as partly accidental, since the relative values of the reference standards used in the two laboratories could not be depended upon to such a high degree of accuracy. Expressed in terms of the length of a column of mercury of the same cross-section as the international standard, these two determinations indicated that the absolute ohm would be represented by a column 106.245 or 106.246 cm. long instead of 106.300. It appears certain, therefore, that the absolute ohm is smaller than the international ohm by about five parts in 10,000, and incidentally that determinations of the absolute ohm can be made with the same degree of precision as the international ohm can be established and checked with mercury ohm tubes.

Values of the Ampere

The present international ampere represents the value obtained by the Technical Committee of 1910 as an average of the results found with several different types of voltameter. Since current is transitory, the average result was recorded and is concretely expressed by the value assigned to the Weston normal cell. The international volt being the potential drop in the accepted international ohm with a current flowing which deposited 1.11800 mg. per sec. in the *average* voltameter, the committee found that the average cell had a voltage of 1.0183, and this has since been used as the standard value. Standard cells used in conjunction with resistance standards calibrated in international ohms presumably reproduce ampere values as then obtained.

The voltameters operated by the Bureau of Standards at that time would have established an ampere larger than the average by three parts in 100,000. That is, in these voltameters the deposits of silver were smaller, probably because they were more nearly pure silver. As a result of researches carried out over a period of several years[6] following the London Conference, the precision of the voltameter as a measuring instrument was materially improved, but since these improvements in procedure reduced the deposits they would increase the value of the ampere as measured by the silver deposited. Seven series of measurements made in five different countries since 1910 have shown an average deviation of only one part in 100,000 from their mean, but the mean is three parts in 100,000 different from the 1910 value. That is, these voltameter measurements would have made the standard cell value 1.01827 instead of 1.0183.

As has been remarked above, the ultimate value of the international ampere as defined by the silver voltameter is as yet indefinite because no precise specifications for the operation of the voltameter have been adopted. The Bureau of Standards has proposed specifications which are believed to assure the highest attainable

degree of purity in the deposit. In voltameters used according to these specifications, the absolute ampere as measured by the Bureau's current balance was found to deposit 1.11804 or 11.1805 mg. per sec., of which about 0.004 per cent was foreign matter included with the silver. Consequently, according to these measurements, if the international ampere were based on *pure silver* deposited, it would be identical with the absolute unit within the limits of accuracy of these measurements.

This allowance for inclusions was not made, however, when the accepted value for the standard cell was established in 1910. Since it has to be added to the difference of three parts in 100,000 mentioned above, the "international ampere" then set up was smaller than the absolute by seven or eight parts in 100,000, according to the measurements made at the Bureau of Standards. Taking into account also measurements at the British National Physical Laboratory[7] and at the University of Groningen, Holland[8], it has been estimated[1] that the best value for the international ampere of 1910 was 0.99991 absolute ampere, and this conversion factor has been commonly used.

There are several distinctly different methods by which the absolute ampere can be found. Since the 1908 London Conference, good determinations have been made by the tangent galvanometer[8], the electrodynamometer[9], and several forms of current balance[7,10]. It is not possible, in most cases, to compare the results exactly because there have been no common standards of sufficient accuracy to preserve and express the values obtained by these experiments. The differences have been a few parts in 100,000, and it is a question how much of these differences is due to the errors in establishing the absolute ampere and how much to variations between the voltameters (or the standard cells and resistance coils) used to represent the international ampere. Certainly it is possible to establish the absolute value within two or three parts in 100,000 with a single instrument like the current balance. If several laboratories were to set up different types of absolute instruments and systematically compare the results, it should be possible to establish and maintain the ampere to one part in 100,000.

Values of the Volt and Other Units

Although the ampere is the second fundamental unit adopted, the unit actually maintained for practical measurements is the volt, as represented in the standard cell. Since 1910 the Bureau of Standards has maintained this unit by groups of reference cells in a manner closely analogous to that described above for the ohm. With a few substitutions of stable cells for some which showed a relative decrease in electromotive force, it is believed that these reference groups of selected cells have remained substantially constant for many years, some of them since 1906. A few new cells have been made recently, and these have agreed with the older groups within one part in 100,000. Results of comparisons with other laboratories in this country and abroad have also generally supported the belief that the Bureau's cells have maintained their values. During the last year, however, differences of several parts in 100,000 have arisen between the Bureau's measurements and those of the National Physical Laboratory, and no complete explanation for them has yet been found.

The absolute value of the international volt and of other international units is, of course, dependent on that of the ohm and of the ampere. On the basis of the estimates given above for the two fundamental units as established in 1910, the various international units have the following values[3]:

1 international ohm	1.00052 absolute ohm
1 international ampere	0.99991 absolute ampere
1 international volt	1.00043 absolute volt
1 international watt	1.00034 absolute watt
1 international joule	1.00034 absolute joule
1 international coulomb	0.99991 absolute coulomb
1 international farad	0.99948 absolute farad
1 international henry	1.00052 absolute henry
1 international gilbert	0.99991 absolute gilbert
1 international maxwell	1.00043 absolute maxwell

Future Units and Standards

There are few applications in which a change of one-twentieth of one per cent (the maximum discrepancy existing between the two sets of units) would now be of any practical importance. The demands of industry for precise measurements have grown with surprising speed, however, and if the discrepancy is ever to be removed, it would be well to perform the operation before the change does become significant in industry. For those laboratories which carry on work of high precision, the changes involved in going over to the absolute units would undoubtedly be troublesome for a time, particularly because so much apparatus is precisely adjusted to values in the international units. The easier course at present would be to retain the old units, making such minor adjustments as may be found necessary for better international agreement, and to establish accurately the necessary conversion factors for those who must transfer from electromagnetic quantities to electrostatic and to heat or other mechanical units. When one considers, however, that this probably means laying up trouble in increasing amounts for decades to come in order to avoid some temporary inconvenience, it would appear that the logical course is to adopt the absolute units in the near future rather than to make merely minor adjustments in the international units.

Before the absolute units could be thus adopted for practical use, it would be necessary to have more laboratories set up apparatus to give these units and to

find whether these newer determinations agreed satisfactorily with those which have been mentioned above. If such apparatus is set up in the several national laboratories and gives concordant results with a certainty as great as that of the mercury ohm and silver voltameter, the need for these inconvenient custodians of the units will have vanished. This will be true even if the present international units should be continued in use.

In the enactment of legal definitions, the concreteness of the standards representing the present international units offers some advantage, but in those countries having national laboratories there should be no serious difficulties in securing the legal recognition of units defined in terms of the centimeter, gram, and second, to be established and maintained by the national laboratory in cooperation with the International Committee on Weights and Measures. Other countries could define the units similarly and provide for obtaining copies of standards through the International Committee.

Although this Committee has never heretofore dealt with electrical standards, it was empowered to do so by an amendment to the international convention on weights and measures which was ratified by the United States in 1923. In accordance with its enlarged authority, the Committee is now inaugurating a series of systematic intercomparisons between the national standardizing laboratories, and it will consider eventually what steps shall be taken to coordinate more effectively electrical measurements as made in different countries.

Whatever course is followed, it is obvious that there is urgent need for comprehensive experimental studies, including the reexamination and further development of the fundamental standards whereby the units are established and maintained. This, of course, is primarily a problem for the national standardizing laboratories. In general, however, such laboratories in recent years have been pressed with problems of more immediate and obvious industrial usefulness, or their means available for fundamental scientific work have been otherwise curtailed.

Present Work at the Bureau of Standards

In view of the long period over which the units have been maintained at the Bureau by means of secondary standards, coils, and cells, it would be desirable to check their values by new mercury-ohm and silver-voltameter determinations. It has been believed, nevertheless, that a revival of the researches on fundamental units is still more important, and that if successfully carried out, these researches would in effect give also as accurate a check on the international units as could be got by the use of the mercury column and the voltameter. Since it has not been practicable to take up work on both types of standards, attention has been given first to the development of apparatus for establishing the fundamental units. Of these units, the ohm has been given priority because the Bureau has never made any determinations of its value, and very few accurate determinations have ever been made. Two independent schemes for accomplishing this purpose are being developed. Both will use stationary inductance coils designed for calculation of the inductance from dimensions. One method, devised some years ago by Dr. Frank Wenner, will use mutual inductances so arranged that the electromotive force induced in the secondaries can be balanced against the potential drop in a resistance of which the value is to be determined. The other procedure is planned to make use of the experience of the Inductance Laboratory under the charge of Dr. H. L. Curtis. It will consist essentially of the comparison, by a-c. bridge methods, of a self-inductance of calculated value with the resistance to be measured. In each project, it is desired to carry the results to an accuracy approaching one part in 100,000, and this requires a theoretical and experimental study of many details which are neglected in ordinary measurements. Fair progress is being made, but it is impossible to predict when final results will be obtained.

For absolute measurements of current, the balance used by Dr. E. B. Rosa[10] and his associates has been reassembled and is being studied for possible improvements. It is hoped that this will soon give results which, in conjunction with the wire ohm standards, will serve to check the Bureau's standard cell values.

Whatever primary standards are used, the cells always serve as one of the essential secondary standards, and studies of their behavior are being made. This work, as well as the maintenance of the reference group of cells, is under the direction of Mr. G. W. Vinal.

Conclusion

This summary of the present situation in regard to the electrical units and standards has been offered because the Bureau of Standards has a large responsibility for their maintenance and improvement which in recent years it has not been able to meet to its own satisfaction. The kind of work necessary to give the accuracy desired in the basic standards can not be done hastily, and it will require several years of work on the part of all the national laboratories to provide a good technical basis for a final decision on the type of standards and on the units to be adopted for international use. Detailed results of the several investigations mentioned will be published as they become available. In the light of these results and those of similar work abroad, the International Committee on Weights and Measures will have to reach a decision. In the meantime, it is desired that those whose interests will be affected by

this decision study the situation and make known their views as to the course which should be chosen.

Methods Used in Investigating Corona Loss
By Means of the Cathode Ray Oscillograph

BY W. L. LLOYD, Jr.[1] and E. C. STARR[1]
Associate, A. I. E. E. Non-member

Synopsis.—*Methods of employing the cathode ray oscillograph for investigation of corona loss are described. By deflecting the ray of cathode particles (electrons) in one direction within the tube by a voltage proportional to the applied voltage, and in a transverse direction by a voltage proportional to the current, a closed figure representative of the loss, is thrown upon the screen. Methods of obtaining photographic records of these figures and of calculating, therefrom, accurate values of the power expended are given. The instrument used is well adapted for this work. Power measurements of 0.1 watt can be measured with an accuracy of 1 per cent.*

From the volt-ampere cyclograms the characteristics of the positive and negative loss on the a-c. wave are readily observed. The instantaneous voltage at which the loss starts and the instantaneous values of the combined corona and capacity currents can be accurately determined.

Measurements of the corona starting point and loss on various conductors check the laws of corona established by Mr. Peek in 1910. The formulas of "critical disruptive gradients" and "visual disruptive gradients" were closely checked. The loss was found to follow a quadratic above the visual critical corona voltage, e_v. For cables and roughened conductors the excess loss below e_v due to surface irregularities approximately follows the probability law. For smooth, polished conductors the loss suddenly jumps from zero to a definite value at e_v and then follows the quadratic.

The practical effect of the condition of the conductor surface is forcibly brought out by the following data measured on a 336,400-cir. mil. cable at 63.5 in. spacing to neutral plane:

Introduction

THIS paper describes in detail the methods used in an investigation of corona loss with the low-voltage cathode-ray oscillograph. The work, which has been under way for several years in the High Voltage Engineering Laboratory at Pittsfield, Mass., is a continuation of the investigation of corona started by Mr. F. W. Peek, Jr. in 1910.[2] It is hoped that this detailed description of the methods employed in using the cathode ray oscillograph and making the laboratory measurements will be of assistance to other investigators. A discussion of the results and the conclusions are given in Mr. Peek's paper, *Law of Corona—IV*.[3]

In studying the corona discharge it is highly desirable to make use of an instrument having no power-factor limitations. It is also desirable that the instrument be capable of accurate indications when the current and power involved are small and the voltage high. The low-voltage cathode ray oscillograph is such an instrument.

The Cathode Ray Oscillograph

This instrument depends for its operation upon a jet, or ray, of cathode particles (electrons) moving at high velocity within an evacuated tube and impinging upon a fluorescent screen. The electrons are discharged from an incandescent filament (the hot cathode). Under the action of a strong electric field, the electrons are rapidly accelerated toward the anode. A small hole in the anode permits certain of the electrons to pass along the axis of the tube in a narrow beam. This beam, or ray, of cathode particles, which subsequently passes between two pairs of metallic plates upon which voltages can be impressed, can be deflected from its normal course by transverse electrostatic or electromagnetic fields, or by a combination of such fields, and thereby made to trace definite figures on the fluorescent screen which becomes luminous at the point at which the electrons strike. These figures are representative of the electrical phenomena taking place within the circuit being investigated, and can be accurately interpreted when the various tube and circuit constants are known. The figures are accurately traced irrespective of the frequency of voltage or current producing the deflections of the electron beam, for this beam has practically no mass and hence no natural period, at least within the limit of the higher radio frequencies.[4]

Photographic Records. Although not strongly luminous, the figure traced on the screen of the tube can be photographed. A sharp image can be obtained by using a lens but the length of exposure required is very great (3 min. or longer). Consequently this method is not desirable when a large number of records is to be taken.

An accurate but somewhat blurred image can be obtained with a comparatively short exposure by operating the tube in a darkened room or box and placing the emulsion side of a "super. speed" photographic film directly in contact with the end of the tube. The exposure required is about $^1/_{10}$ to $^1/_4$ sec. for a

straight line image, and about ½ sec. for other figures. The exposures are made by bringing the filament of the tube up to the proper temperature and then closing the anode circuit for the required length of time.

Tube Calibration. The construction of the tube is such that the deflection of the cathode beam as shown on the screen of the tube is approximately proportional to the maximum voltage difference between the deflector plates. Photographs were taken of the individual deflections, horizontal and vertical, for various

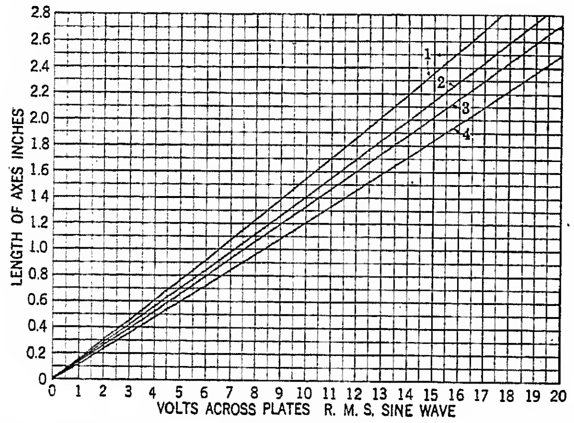

Fig. 1a—Calibration Curves for the Cathode Ray Oscillograph

1—Vertical deflection—anode potential 241.5 volts
2—Horizontal deflection—anode potential 241.5 volts
3—Vertical deflection—anode potential 315.0 volts
4—Horizontal deflection—anode potential 315.0 volts

known sinusoidal plate voltages and different anode potentials. These films were measured and curves plotted showing the relationship between deflection, horizontal and vertical, and deflector-plate voltage. See Fig. 1.

It was thought that possibly the calibration might vary over different parts of the screen, but simultaneous exposures of the axes, producing straight diagonal lines across the screen, and photographs of the individual axes displaced as far from the center as practical, indicated that there was little or no change in the calibration.

Corona Loss Measurements

Volt—Ampere Cyclograms. The most satisfactory arrangement for studying corona losses by means of the cathode ray tube has been found in this investigation to be that shown diagrammatically in Fig. 2. A specimen of the conductor to be studied was suspended vertically at a uniform spacing from a broad, vertical metal plate having a length of about 20 ft. This plate was composed of three sections of equal width. The end sections, each five ft. in length, were grounded and the middle section, which was insulated from the other two, was grounded through the variable non-inductive resistance, R_3. The function of the end sections was to intercept the corona discharges from the ends of the conductor and leave a uniform section exposed to the active plate.

Although this ground plate, which served as a part of the neutral plane, was 5 ft. wide, it was rather narrow relative to some of the spacings used in the tests. In the near vicinity of the set-up there were several other grounded objects (principally a metal wall) which were, in effect, extensions of the ground plate. Consequently the active section of the plate was only a part of the practically infinite neutral plane, and therefore intercepted only a fraction of the flux emanating from the conductor. The relative amount of flux intercepted became less as the spacing was increased. The object of this work, however, was to study the critical voltage, the mechanism of the discharge, and the relative rather than the absolute value of the losses. For this purpose the set-up was found to be entirely satisfactory.

The step-up and potential transformers were identical, and were rated 10 kv-a., 25-cycle, 200/100,000-volt. These transformers were capable of delivering 150,000 volts intermittently without injury and, when operated at 60 cycles, without high flux density in the core. Voltage control was obtained by means of variable resistances in series with the low-voltage winding of the step-up transformer. Resistances are very flexible, and give practically no wave distortion when used in connection with a load of constant impedance, as in these tests. A constant-impedance load, consisting of high-voltage condensers of a total capacity of about 0.00125 μf., was shunted across the

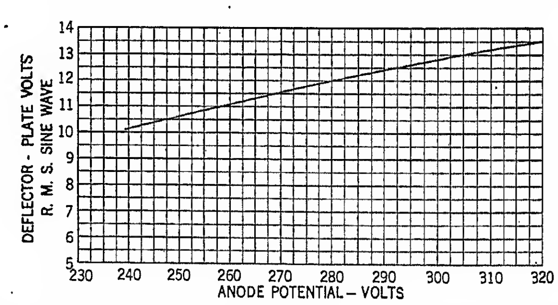

Fig. 1b—Curve Showing The Relation Between Deflector-Plate Voltage to Produce a Vertical Deflection of 1.8 in. (Pos. + Neg.) and Anode Potential of Tube

high-voltage winding. This was a load several times as great as that imposed by the exciting kv-a. of the transformers plus the maximum corona loss obtained. The function of this capacitance was to smooth out the voltage wave impressed on the conductor. It accomplished this by supplying the magnetizing current of the transformers and by providing a heavy sinusoidal current to minimize the disturbing influence of the non-sinusoidal corona currents.

A resistance potentiometer, consisting of two non-inductive variable resistances, R_1 and R_2, was shunted across the low-voltage winding of the potential transformer and provided a means of obtaining a voltage of the desired value across the deflector plates of the

cathode ray tube. The voltage thus obtained was for any particular setting of R_1 and R_2 proportional to and in phase with the voltage impressed on the corona conductor.[5]

The voltage drop across R_3 was proportional to and in phase with the current flowing to ground from the middle section of the test conductor and was impressed across the remaining pair of deflector plates.

Since the corona phenomena are re-occurring, the figures traced on the screen of the oscillograph tube

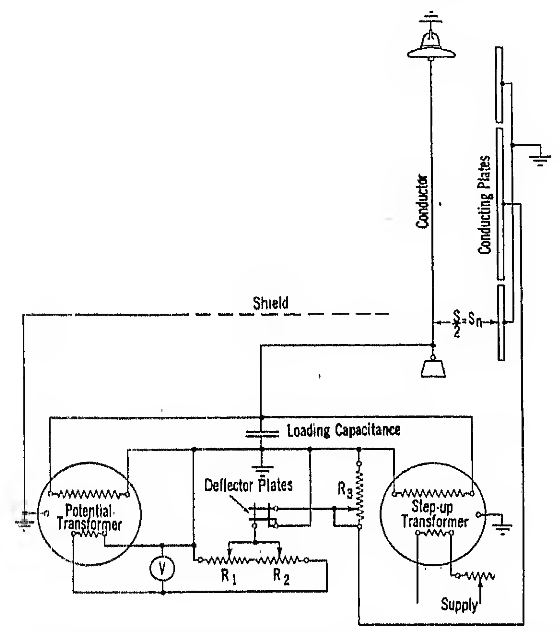

FIG. 2—DIAGRAM OF CONNECTIONS FOR A STUDY OF CORONA BY MEANS OF THE CATHODE RAY OSCILLOGRAPH

under the above conditions are stationary and are accurately indicative of the instantaneous relationships between voltage and current. When no corona exists, both the current and voltage waves are sinusoidal and 90 degrees out of phase as dry air is practically a perfect dielectric. The figure traced on the screen is then a pure ellipse. With the connections as shown in Fig. 2 the abscissas of the ellipse are proportional to voltage and the ordinates proportional to current. The cyclogram in Fig. 3A illustrates this condition. The individual axes were obtained by grounding one pair of deflector plates at a time and thus obtaining each separate deflection independent of the other. When corona is present on the test conductor the voltage remains sinusoidal but the current wave is badly distorted. An individual discharge takes place during each half-cycle of voltage, near the crest of the wave if the impressed voltage is only a few per cent above the critical disruptive value. These discharges appeared on the screen of the tube as an irregular "hump" on each half of the figure. The circuit employed was such that the lower right hand hump represented the discharge during the time that the conductor was negative. The upper left hand hump represented the positive discharge. The cyclogram in Fig. 3B illustrates this condition for a voltage slightly in excess of the visual critical value.

A permanent record of the figure traced by the electrons on the screen of the tube was most easily obtained, as noted above, by placing a "super speed" photographic film in contact with the end of the tube. The film was first placed in position in the dark box containing the tube. The tube was then moved ahead by means of an adjusting screw and forced into contact with the film. The filament of the tube was heated to the proper temperature, the required current having been determined previously by means of the filament

ammeter and visual inspection of the figure on the screen. The desired voltage was then impressed on the test wire. One pair of deflector plates was grounded and the anode circuit closed for approximately ¼ sec. The first pair of plates was then connected in circuit and the other pair grounded, and another ¼-sec. exposure made. Both pairs of plates were then connected in circuit and an exposure of about ½ sec. was made. In this way a record of the figure

5. The phase angle and ratio errors of a high-voltage transformer when operating at low core densities on no load as a step down transformer are very slight and, for this investigation, can be neglected.

and both axes was obtained. The film was developed in the usual manner.

In order that the voltage drop across R_3 be proportional to and in phase with the current flowing to ground from the middle section of the ground plate, it was essential that there be relatively no capacitance or inductance in this part of the circuit. Since the ground capacity of the active section of the ground plate was approximately $4.9 \times 10^{-4} \mu$ f. and was, in effect, shunted across R_3, the value of this resistance, which was non-inductive, was kept less than 100,000 ohms. Consequently the maximum phase-angle error introduced was less than one degree.

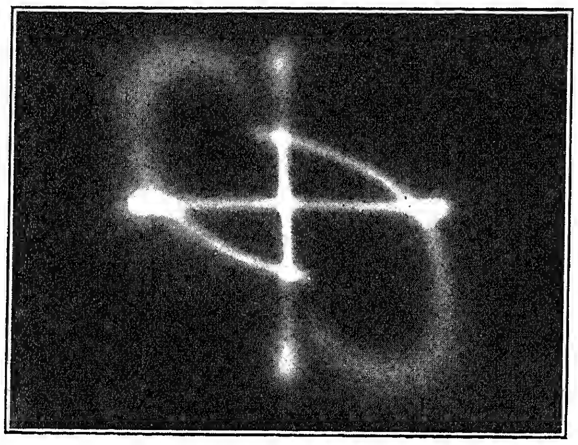

Fig. 4—Volt-Ampere Cyclogram of Heavy Corona

Conductor; No. 00 polished conductor
Spacing; 21.5 in. to neutral
Voltage; 150 kv. (eff.) to neutral

A grounded network was placed above the bushings of the transformers to shield out stray fields which otherwise would have reached the effective section of the ground plate.

Most of the work was done at 60 cycles but some measurements were made at 420 cycles. Practically the same test circuit was used in both cases. At normal frequency, even with the loading capacitance removed, the system drew a leading current, but at 420 cycles the impedance of the step-up transformer was so increased and the impedance of the high-side load so decreased that the system drew a lagging current. It was necessary, then, in order to reduce the current drawn from the supply lines to a minimum, to remove the extra capacitance from the high side and shunt a large capacitance across the low side of the step-up transformer.

The sources of power for all of the tests, both 60 and 420 cycles, were sine-wave alternators of large capacity.

Analysis of Cyclograms. Since the abscissas of the cyclograms are proportional to instantaneous voltage, and the ordinates proportional to instantaneous current, if the wave shape of one of the two quantities is known the other can be plotted with time as abscissa and the unknown quantity as ordinate. Fig. 5 illustrates a case in which the horizontal deflection was produced by a known sinusoidal voltage (a voltage proportional to and in phase with the voltage of the test conductor) and hence the current wave, in both magnitude and phase, was readily derived, as shown, from the cyclogram. The original cyclogram from which Fig. 5 was taken is given in Fig. 4.

As well as giving an indication of the wave form of the current in the corona discharge, the cyclograms also provide an accurate means of determining the instantaneous voltages, positive and negative, at which corona forms on the conductor. In Fig. 6, E_i (pos.) and E_i (neg.) represent these voltages.

Since the discharges fade out very gradually, the cyclograms give no definite indications of the exact stopping points. It is evident, however, that the discharges do not persist far beyond the crests of the voltage waves. As brought out later, the stroboscope verified this point.

The maximum charging current of the conductor due merely to the normal conductor capacitance and the maximum *rate of change* of voltage for that particular maximum voltage is represented (approximately) by I_c (max).

The maximum currents occurring during the discharge are represented by I_{max} (pos.) and I_{max} (neg.).

The rotation of the cathode beam in generating this general type of cyclogram is, as viewed normally, counter-clockwise.

Stroboscopic Observations

In order to obtain an approximate check on some of the discharge characteristics disclosed by the cathode ray tube, a stroboscope, or synchronous shutter, was used to permit visual inspection, in a darkened room,

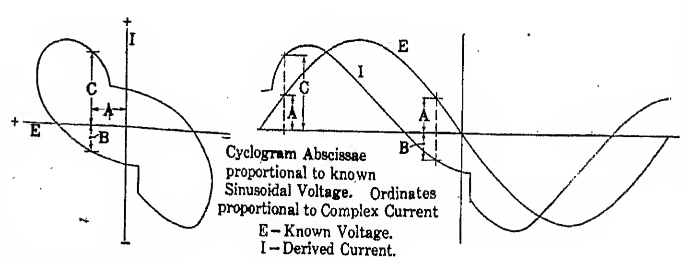

Fig. 5—Graphical Analysis of the Volt-Ampere Cyclogram Shown in Fig. 4

Cyclogram abscissas proportional to known sinusoidal voltage. Ordinates proportional to complex current
E—Known voltage
I—Derived current

of the corona discharge from a polished conductor at any point on the voltage wave. These observations checked the instantaneous disruptive voltages very closely, and indicated definitely that the discharges terminate shortly after the passing of the voltage crests. The corona "sparks" are most intense when they first appear. The illumination then gradually fades out and

disappears at a point 10 to 25 deg. beyond the voltage crest.

Power Calculations

When taken by means of the circuit shown in Fig. 2 the cyclograms obtained are volt—ampere curves, the horizontal deflections being practically proportional to and in phase with the sinusoidal line voltage to ground, and the vertical deflections practically proportional to and in phase with the complex current flowing between the conductor and ground plate.[6] The average power represented by the cyclogram can then be calculated by the method outlined below.

The figure is divided into a convenient number of equal-time sections, and the product of the mean abscissa and the estimated mean effective ordinate is obtained for each section. The sign of each of these products is determined algebraically from the sign of the factors, the abscissas being positive to the left of the vertical axis and the ordinates positive above the horizontal axis. The algebraic mean of these products is then proportional to the average power expenditure, and when multipled by the product of average volts per unit horizontal deflection and average amperes per unit vertical deflection is expressed in watts. This process is rather involved but, since the current waves are quite complex, it is the only accurate method of calculating the power represented by the figures.

The current and voltage factors are obtained from the constants of the test circuit, the tube calibration curves, and the line voltage. The voltage factor is equal to the maximum line voltage divided by the maximum horizontal deflection (positive or negative) in units. The current factor is equal to the deflector-plate volts

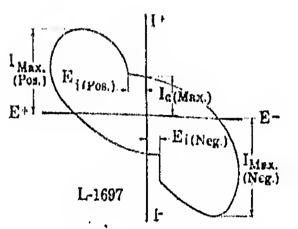

Fig. 6—Corona Discharge Characteristics as Indicated by the Volt-Ampere Cyclogram

E_i Proportional to instantaneous disruptive voltage
I_{max} Proportional to maximum current
$I_{c(max)}$ Approximately proportional to maximum conductor charging current

(maximum) per unit vertical deflection (obtained from the tube calibration curves) divided by the value of R_3 in ohms. The calculation of the unit current constant was simplified by the use of a curve plotted for a given set of conditions and made applicable to other conditions by means of a simple formula.

It has been found that sufficient accuracy is usually obtained by dividing the cyclograms into 20 equal-time sections. Each section then represents 18 degrees of the cycle. The instantaneous voltage at the mid point of each section is very nearly the average voltage

cally proportional to deflector-plate voltage, the horizontal axis of the cyclogram, Fig. 8, is then divided at $u, -u; v, -v; w, -w; x, -x; y, -y$, according to the equation:

$$D_\theta = D_m \sin \theta$$

where D_θ = Horizontal deflection, positive or negative, at angle, θ, as above.

D_m = Maximum positive or negative horizontal deflection.

Ordinates of the figure corresponding to the abscissas $u, -u; v, -v$; etc., are taken as the points of intersection of the figure with vertical lines drawn through these abscissas, for all sections except those containing an abrupt break in the rate of change of the ordinate, or those having such a nature that the ordinate obtained in this manner is obviously not the approximate mean value for the section. An accurate estimate of the mean ordinate of a section having an irregular boundary is obtained by joining the limits of the given section by a straight line and taking the average ordinate of the straight line and the curve at the given abscissa as the value for use in the subsequent calculations. In this illustrative example (Fig. 7), a is the ordinate taken to correspond to abscissa u (dotted line joins limits of section), and c to correspond to abscissa w.

When obtained by means of the tube in use at present, the horizontal axis is not exactly a straight line, nor is either half of it perpendicular to the vertical axis. It is most convenient, therefore, when tracing the figure from the photographs on transparent coordinate paper, to place the vertical axis in coincidence with the axis of ordinates, and the horizontal axis in its true position, the origin being the intersection point of the vertical and horizontal axes. In measuring the ordinates it is necessary to take the displacement of the axis of abscissas into account.

Since vertical deflections above the horizontal axis represent current in the positive direction, and horizontal deflections to the left of the vertical axis represent voltage in the positive direction, the first quadrant represents negative power, the second positive, third negative, and fourth positive.

A complete example of the power loss calculations on a typical cyclogram is given in Fig. 7. Space is not available for including the derivation of the formula used, but it is simple and was developed in order to expedite the calculation of numerous cyclograms.

This method of calculating power expenditure is, in effect, the same as that of transcribing the figures to rectangular coordinates and integrating the power wave in the customary manner. Fig. 8 gives an example of the two methods of calculation as applied to the same cyclogram.

To one who had little or no experience in making these calculations it will seem, on account of the blurred figure with which one has to work, that the accuracy would be poor, but such is not the case. After a small amount of practise one can estimate the centers of the lines very accurately, and it has been found that different individuals working independently and at different times will obtain results that check within one per cent. Power values as low as 0.1 watt can be measured with this same accuracy.

A slight error is introduced in the results obtained by means of the methods illustrated in Figs. 7 and 8 by the deviation of the cathode-beam deflection from a linear function of the deflector-plate voltage. This error is, for all practical purposes, inappreciable and the error in abscissas practically compensates for that in ordinates. Under some circumstances, however, it may be desirable to make more exact calculations and a brief outline of this method follows:

The abscissas of the mid-point divisions on the hori-ntal axis of the cyclogram are located by determining, m the proper calibration curve, the deflector-plate ltage necessary to produce the maximum abscissa of e figure; multiplying this value by the sines of the id-point angles; and determining, from the calibra-n curves, the deflections corresponding to these oducts. At these new abscissas, the average ordi-tes are read and each one is multiplied by the ratio of erage deflector-plate volts per unit required to oduce that ordinate to average volts per unit to oduce the maximum ordinate. The current and

ltage factors are determined from the maximum flections as before.

It should be noted that in obtaining the various oducts of abscissas and ordinates the value of ab-issa required is, for instance, maximum deflection ax. abscissa) times sin 9 deg., etc., and not the rrected abscissa from which the corresponding rrent is obtained, and the ordinate is the corrected lue as given above.

These corrections, the effects of which are very slight, re not made in the loss data given in this paper.

Volt-Coulomb Cyclograms. The corona phenomena n be studied from a somewhat different angle if the resistance, R_3, in Fig. 2 is replaced by a capacitance C_3, or by a parallel combination of capacitance and high resistance C_3'. The ordinates of the cyclograms obtained are then proportional to the instantaneous charges induced on the ground plate by the voltage on the conductor.

If pure capacitance is used, the figure will drift over the screen of the tube due to the accumulation of a negative charge on the deflector-plate connected to C_3. Since in the case of 60-cycle corona on conductors at relatively close spacings, the positive and negative discharges are of unequal magnitudes, C_3 will accumulate a positive or an additional negative charge which will cause further drifting of the figure. In the case of a small conductor (0.015 in. diam.) at a fairly close spacing (7.5 in. to neutral) it was found that at about 15.0 kv. to neutral the positive excess was just sufficient to compensate for the negative charge acquired from the electron stream within the tube. Consequently the figure would remain stationary near the center of the screen and could be photographed when the line and anode voltages were properly manipulated.

When a high resistance is shunted across C_3 to provide a leakage path for the excess positive or negative component, the figure remains stationary at all voltages, and can be photographed in the usual manner.

Fig. 9A is a volt-coulomb cyclogram of the discharge characteristics of a 15-mil (0.015 in. diam.) conductor spaced 7.5 in. to neutral and operating at 15.0 kv. to neutral. This figure was generated in the clockwise direction. The approximately parallel top and bottom sides of the figure represent the 60-cycle charge (affected somewhat by the motion of the space charge surrounding the conductor) induced on the ground plate by the normal conductor capacitance. The slightly curved end sections represent the excess charge induced during a part of each half cycle by the periodically increased conductor capacitance. This increased capacitance exists only during the discharges and hence disappears near the crests of the voltage waves. Consequently the excess charges can not be returned to the circuit and are lost.

This type of cyclogram has been employed in other corona investigations, notably those of Dr. Ryan, and provides a convenient means of studying the phenomena from the standpoint of the charge and discharge of "space condensers," but is not so convenient as the first type for power calculation purposes.[7]

A volt-ampere cyclogram corresponding to Fig. 9A is given in Fig. 9B.

POWER LOSS DATA

By means of the first method described above (*i. e.* the volt—ampere cyclograms), loss measurements were made on several solid conductors of various sizes under different conditions of spacing and surface regularity, and also on a large, concentric-strand cable. Typical data are given in Tables I and II and on the accompanying curves.

Fig. 10 gives the 60-cycle loss characteristic of a very small, smooth wire (0.015 in. in diameter) at a rather close spacing (7.5 in. to "neutral"), and at voltages up to the arc-over value. It will be noted that the curve of square root of power against line voltage is very nearly a straight line for a considerable distance above the point marked e_v indicating that in this region the loss followed a quadratic law quite closely. Near the upper end this curve turns up rapidly, indicating that the loss increased at a higher rate just preceding arc-over. Dirt and oxide on this conductor had practically no effect on the loss above e_v. The effective diameter of the conductor was probably sufficiently increased by the foreign matter to compensate for the irregular surface.

Figs. 11 and 12 give the 60-cycle loss characteristics of a large, solid conductor (0.365 in. diameter), both polished and rough, at two spacings (63.5 in. and 21.5 in. to neutral). The curve for the roughened conductor in Fig. 11 was plotted from the data given in Table I, and the curve for the polished conductor in Fig. 12 was plotted from the data given in Table II. No loss whatsoever could be detected from the polished conductor until the visual critical voltage was reached. At this point it suddenly jumped to a definite value and then, with further increase of voltage, followed a quadratic law very closely. It will be noted that for this conductor at the closer spacing two critical voltages are indicated, one for increasing voltage and a different one for decreasing voltage. This characteristic seemed quite definite in the case of large polished conductors at small spacings, and was probably an effect of the space charge created by the uniform corona

envelope. The roughened conductor gave a loss at much lower voltages than the polished, and a greater loss at the higher voltages. In this case the loss apparently followed no definite law, and was very sensitive to accidental surface conditions until well above the starting voltage when the curve became a quadratic.

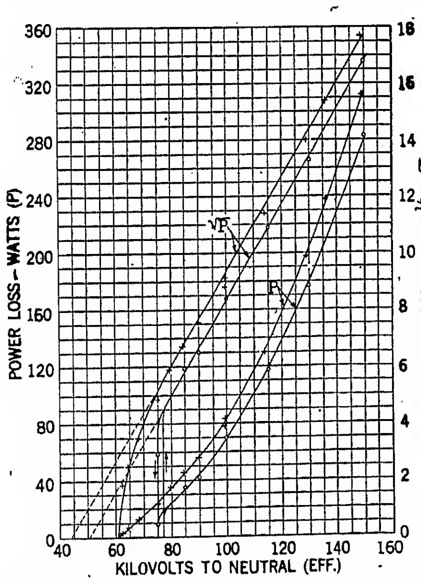

FIG. 12—OBSERVED CORONA LOSS, MEASURED BY MEANS OF THE CATHODE RAY OSCILLOGRAPH

The excess loss above the quadratic due to surface irregularities gave a typical probability curve.

Loss measurements were made on a 336,400-cir. mil A. C. S. R. (aluminum conductor steel reinforced) cable with the surface in three different conditions, namely, smooth, rough, and mutilated. A smooth, clean cable spaced 63.5 in. to neutral gave no loss below 119.0 kv. to neutral and closely followed the quadratic, for $m_0 = 0.85$, above 125 kv. This value of m_0 was about the average obtained with this conductor at the 21.5-in. and 63.5-in spacings. See Table III. In the case of the roughened conductor the outside strands were scratched, as if the cable had been dragged

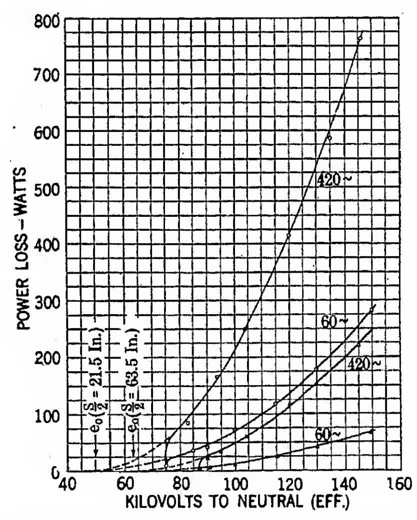

FIG. 13—OBSERVED CORONA LOSS—MEASURED BY MEANS OF THE CATHODE RAY OSCILLOGRAPH

△ = 63.5 in.

Length: 10.0 ft.

over rough ground, and were covered with spots of dirt and oxide. The loss started at a lower voltage (89 per cent of the former starting value) and was higher over the entire range. The outside strands of the mutilated conductor were in a condition such as would be produced by dragging the cable over hard

sharp rocks. The loss started at a very low voltage (53 per cent of the starting value for the smooth conductor) and was of greater magnitude than in the other two cases.

It was found that the curve obtained by subtracting the quadratic from the loss curve of the mutilated conductor was a typical probability curve. Extrapolation of the curves for the three conditions beyond 150 kv. (up to which voltage the measurements were taken) showed them to come approximately together at 185 kv.

The loss from the smooth cable had much the same characteristics as that from the roughened solid conductor (Fig. 13). The surface irregularities, in the former case due to stranding and in the latter case due to burrs and scratches, caused the loss to begin below the "visual critical voltage," e_v, (for a smooth conductor of the same diameter) but not so low as the critical disruptive voltage, e_0. The quadratic seemed to apply when the true critical voltage, e_v, was approached. As was mentioned in connection with the solid conductors, the loss from the cables at voltages below e_v was very sensitive to changes in surface condition. When the strands were badly scratched the loss started at a relatively low voltage, far below the value of e_0 for the smooth cable, and was of considerable magnitude at voltages too low to cause any discharge from the undamaged conductor.

It is of interest to study the data obtained with the above three specimens of cable and the following conclusions are of particular interest:

1. At e_v, corresponding to a three-phase line voltage of 258,000 volts, the loss from the smooth cable was 49 kw. per mile of conductor.

2. At 220,000 volts, three-phase, the loss from the smooth cable was 18.0 kw. per mile and from the rough cable was 29.4 kw. per mile.

3. At 205,000 volts, three-phase, there was no loss from the smooth cable, 17.0 kw. per mile loss from the rough cable, and 38.0 kw. per mile loss from the mutilated cable.

4. At 132,000 volts, three-phase, the loss from the mutilated cable was 4.7 kw. per mile of conductor.

5. At sea level and in fair weather the smooth cable would operate at 205,000 volts, and the rough cable at 180,000 volts, three-phase, without corona loss. Corona would still be present on the mutilated cable at 130,000 volts, three phase.

From the above data it is evident that a great deal of care should be exercised in stringing the lines in order to keep them as free as possible from burrs and scratches. It is also evident that small changes in the surface condition of the conductor produce large changes in the magnitude of the loss near the critical voltage. The deviation of the loss curve from a quadratic below e_v seems to follow the probability law and, since the loss below e_v is determined by the size, projection, and number of irregular "spots" on the conductor, it is reasonable that this law *should* apply, at least approximately.

It seems that the best general practise is not to attempt to design the line for a given amount of corona loss, but to so choose the conductor and spacing that the dielectric strength of air (*i. e.*, 30 kv. per cm. max. under standard atmospheric conditions) multiplied by the irregularity factor of that conductor is not exceeded at the conductor surface for the highest operating voltages. Recent developments in the manufacture of cables having large diameters relative to their effective cross sectional areas make it economically possible to design and construct corona-free lines.

The irregularity factor is determined by actual measurement on a specimen of the given conductor or a similar conductor which has been installed and well weathered under the particular conditions involved.

Radio interference, and interference with successful carrier-current communication on the line itself are gaining importance as factors making the elimination of corona an important matter.

Loss at Higher Frequency. Fig. 13 gives the loss characteristics of a large, solid conductor, polished, at 420 cycles in comparison with the same at 60 cycles. The ratio of losses at the closer spacing was about 3 and at the greater spacing was about 3.5. The conduction component of the loss was apparently considerably greater at the small than at the large spacing and probably accounted for the difference in ratios. These curves are quadratics with the same critical voltages as the 60-cycle curves on the same conductor.

Comparison With Results of Previous Investigations

The quadratic law, which was established by Mr. Peek in 1910, was closely checked for voltages above the "visual critical" value (e_v). Below this voltage the deviation from a quadratic of the loss curves for cables and roughened solid conductors was found to follow the probability law closely.

In order to obtain absolute values it is necessary to correct the loss data obtained in these tests because the ground plate did not intercept all the electrostatic flux emanating from the conductor. The correction varies with the spacing. For any given spacing, however, the percentage of flux intercepted by the plate is approximately constant regardless of the voltage.

The correction is readily obtained by comparing the calculated charging current of the conductor with the measured values. In this manner it was found that at a spacing of 63.5 in. to neutral about 44 per cent of the total current was measured, and at a spacing of 21.5 in. to neutral about 78 per cent was measured. The uncorrected measured loss at the greater spacing was about 38 per cent of the value calculated by

means of Peek's formula, and at the smaller spacing was about 70 per cent of the calculated value.

The formulas for critical disruptive gradients and particularly the visual critical gradients as determined by Mr. Peek's early work were closely checked.

The disruptive critical voltage, e_d, which is the voltage at which the quadratic curve starts; the visual critical voltage, e_v, and the actual corona starting voltage, e_c, for a number of conductors are tabulated in Table III. Both the calculated and observed values of the first two quantities are recorded. The calculated values of e_d are from Peek's[8] disruptive critical formulae for $m_d = 1$. The observed values of e_d are the voltages at which the projected curves of square root of power against voltage intersects the voltage axis. The quantity m_d (actual) is the ratio of observed e_d to calculated e_d.

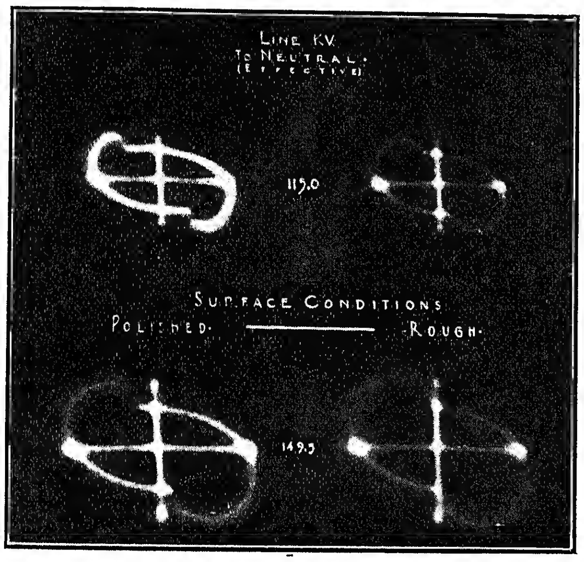

Fig. 14—Comparative Cyclograms Showing the Influence of Conductor Surface Condition Upon Corona Discharge Characteristics.

Conductor: solid, 0.365 in. diameter
Spacing to neutral: 63.5 in.

The observed values of e_v are the voltages at which the losses began to obey a quadratic law: The calculated values were obtained from Peek's visual critical formulae for $m_v = 1$.

Over the entire range of conductors tested, a remarkably close agreement exists between the observed and calculated values of e_v. There is also a fairly close agreement between the observed and calculated values of e_d. It will be noted that in the case of the roughened solid conductors the loss actually started at voltages well above the e_d of the same conductor in a polished condition. The same may be said regarding the roughened cable. For the mutilated cable, however, e_c is lower than e_d ($e_d = e_0$ in the case of large conductors such as this). This condition is largely accounted for by the presence on the cable of numerous sharp projections which produced flux concentrations and consequently, local discharges at relatively low voltages.

8. See "Dielectric Phenomena in High Voltage Engineering," by F. W. Peek, Jr., pages 117-152.

Characteristics of the Corona Discharge

Typical cyclograms showing the discharge characteristics under different conditions are given in Figs. 3B, 4 and 14. It will be noted that for polished conductors (Figs. 4, 14 left side) the individual discharges, particularly the negative, form very suddenly, and the current waves contain abrupt distortions. In the case of roughened conductors (Fig. 14 right side) and cables the individual discharges form much more gradually and the current wave distortions are much less abrupt. Fig. 14 illustrates the influence of surface conditions upon the magnitude and character of the discharge.

The decrease of instantaneous disruptive voltage with increasing line voltage is shown in Fig. 14.

Summary

The low-voltage cathode ray oscillograph is well adapted to investigations of phenomena involving small currents of complex wave shape. This instrument was used in a study of the volt—ampere characteristics of the corona discharge. The circuit employed was such that the figures traced on the screen of the tube were volt-ampere cyclograms. These cyclograms were photographed by placing the film directly against the end of the tube and the power expenditure represented was calculated by a method which was in effect the same as that of transcribing the polar figures to rectangular coordinates and integrating the power wave in the usual manner. The results were converted to watts by means of the tube calibration data which were obtained by impressing definite voltages across the deflector plates and measuring the resulting deflections.

The cyclograms give accurate indications of the structural nature and characteristics of the corona discharge.

Some of these characteristics were checked visually by means of the stroboscope.

The following conclusions were drawn regarding the power loss and starting voltage:

1. Above the "visual critical voltage," e_v, as given in Mr. Peek's early work, the loss-voltage relation is a quadratic.

2. For polished solid conductors the loss suddenly jumps from zero to a definite value at e_v and then follows a quadratic.

3. For cables and roughened solid conductors the excess loss above or below that given by the quadratic law approximately follows the probability law below

e_v. This excess loss may be either positive or negative, or both.

4. The critical disruptive gradients and particularly the visual critical gradients as determined in Mr. Peek's early work were closely checked.

5. The loss near the starting voltage is greatly affected by the regularity and condition of the conductor surface.

The characteristics of the discharge are briefly as follows:

1. For polished solid conductors the individual discharges, particularly the negative, start suddenly and are accompanied by heavy rushes of current.

2. For roughened solid conductors or cables the individual discharges start gradually and the current waves contain no sharp breaks.

3. The instantaneous disruptive voltages decrease with increasing line voltage.

4. The individual discharges stop near the crests of the voltage waves.

Acknowledgment is made of the assistance of Mr. T. M. Hotchkiss, and others of the staff of the High Voltage Engineering Laboratory.

Discussion

The Law of Corona and the Dielectric Strength of Air—IV

The Mechanism of Corona Formation and Loss

BY F. W. PEEK[1]

Fellow, A. I. E. E.

Synopsis.—*The mechanisms of corona and corona loss have been studied with the cathode-ray oscillograph. High voltage power of the order of 0.1 watt can be measured with an accuracy of 1 per cent with this instrument. The measurements show that the loss follows the quadratic law above the visual critical voltage.*

On polished wires there is no loss until the visual critical voltage is reached. The loss then starts quite suddenly and takes a finite value on the quadratic curve. On cables and imperfect conductors there is a loss below the visual critical voltage on brushes at local "rough" spots. The loss due to these irregularities can be represented by the probability law. This is quite in accord with former work.

In practise it is important not to mutilate the conductors in stringing. The really important factor in design is the irregularity factor, m_o, for weathered conductors. No line should be operated with a corona loss under fair weather conditions. It is not necessary from the economic standpoint since large diameters can be obtained with special types of conductors.

The visual critical corona voltage can be calculated with great accuracy. As the applied a-c. voltage is increased above the visual critical value, the instantaneous critical voltage becomes lower and lower until finally corona starts at the zero point of the wave. This occurs when the applied voltage is twice the visual critical voltage. At still higher voltage, corona starts below zero or on the falling wave. The effect is as if the instantaneous critical voltage is reduced by an amount approximately equal to the excess of the applied voltage above the visual critical voltage. Thus when the excess is equal to the visual critical voltage the instantaneous voltage is zero. This occurs when the applied voltage is twice the visual critical voltage. The reason for this is clearly shown as well as many other interesting facts.

Artificial corona was readily produced with all of the characteristics of real corona after the mechanism was determined.

The quadratic law seems to be the rational expression for the loss.

Details of measurements are given in the supplemental paper on measurements by Starr and Lloyd, "Methods Used in an Investigation of Corona Loss by Means of the Cathode-Ray Oscillograph."

INTRODUCTION

THIS paper records the continuation of an investigation started in 1910, first reported to the Institute in 1911[2] and from time to time thereafter as seemed desirable.

At this time the results of a study with the cathode ray oscillograph are given. This instrument, not available in a very practical form when the investigation was started, has now made it possible to obtain a very good picture of the mechanism of corona formation and loss as well as to measure small losses. The instrument used was of the Western Electric hot cathode type. Probably the first work on corona with the cathode ray oscillograph was done by Prof. H. J. Ryan who has added considerably to our knowledge of this subject[3].

RÉSUME AND CONCLUSIONS

The cathode ray oscillograph used in the investigation described in this paper offers a means of studying the mechanism of corona loss as well as a means of measuring accurately small low power factor losses.

This investigation clearly shows the mechanism of corona loss. It was found that the corona loss follows the quadratic law above the visual critical voltage. Below this voltage there is no loss on polished conductors but loss may occur on an imperfect conductor due to local corona at surface irregularities caused by abrasions, dirt, etc. A weathered cable has the characteristic of a dirty wire and may approximate the quadratic down to the disruptive critical voltage. The operating voltage should be below the disruptive critical voltage for the weathered conductor. The losses due to chance irregularities near the critical voltage are closely approximated by the probability law. This quite confirms the results of the former investigations.

The measured visual critical corona voltages check the calculated values very closely.

The cathode ray oscillograms show quite clearly how the corona loss occurs. As the applied voltage is increased above the visual critical voltage, corona starts at a lower and lower instantaneous value of voltage on the a-c. wave. The instantaneous value of starting voltage on the a-c. wave is decreased by an amount approximately equal to the excess of the applied voltage above the visual critical voltage. For instance, when the applied voltage is twice the visual critical voltage, corona starts at the zero point of the voltage wave on each half-cycle. Thus the excess of the applied voltage above e_v is

$$2e_v - e_v = e_v$$

The critical voltage is then decreased by this amount or reduced to

$$e_v - e_v = 0$$

The reason for this is quite evident. After corona starts, a tube of corona surrounds the conductor and

is charged through the "corona arcs" up to the maximum of the wave when the arcs go out or corona stops. This corona tube or "space" charge increases quite suddenly to a finite diameter at the start and then more gradually as the maximum of the wave is approached. This charge caused by the excess voltage returns towards the conductor with the falling wave and adds to the charge caused by the applied voltage on the next half-cycle. When the sum of these charges is

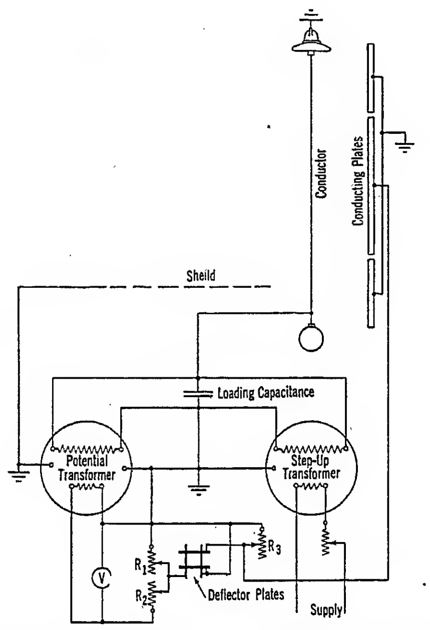

Fig. 1—Arrangement of Vertical Plate and Conductor for a Study of Corona by Means of the Cathode Ray Oscillograph

sufficient to cause the breakdown gradient, corona starts at an instantaneous voltage less than the visual critical voltage. With the start of corona there is a sudden rush of current. When twice the visual critical voltage is applied, the excess voltage is equal to the critical voltage. The charge due to this excess voltage is then sufficient to cause corona without any additional charge. Corona thus starts on the following half-cycles on the zero of the wave as shown above. If the applied voltage is further increased, corona starts below the zero of the wave or on the falling voltage.

Corona characteristics can be produced artificially by means of condensers. For example, take two condensers and place a gap in series with a resistance across one of them. If voltage is applied and gradually increased, capacity current flows until the gap breaks down. There is a sudden rush of current. The spark, which represents the corona, continues to the maximum of the voltage wave when it stops. This leaves an excess charge on one condenser which adds to the charge caused by the line voltage on the next half-cycle. The gap breaks down at lower and lower instantaneous voltage as the applied voltage is increased and becomes zero when the applied voltage is twice the initial starting voltage as in the case of corona.

It is shown that the loss is caused by the charging of the space condenser through the "resistance" of the corona arc or by the motion of the charge through the field and that the quadratic is the rational form for the loss to take.

The formation of corona current is much faster on the negative than on the positive wave.

The results are of practical as well as theoretical importance. For instance, Fig. 7 shows very decidedly the importance of using care in stringing conductors.

Methods of Tests

The cathode ray oscillograph was connected as shown in Fig. 1. With this arrangement the field across one pair of plates is proportional to the voltage while that across the other pair is proportional to the current. When voltage is applied across a capacity load, an ellipse is described, as shown in Fig. 2, the abscissas being proportional to the instantaneous voltages and the ordinates to the instantaneous current. These figures are recorded photographically. The voltage deflections to the left are positive while those to the right are negative. Positive currents cause deflections above the horizontal axis and negative currents below the axis. If the voltage wave is known, the voltage and current waves can be plotted as shown in Fig. 8. Power is easily obtained by measurements of the instantaneous voltage and current and by simple calculations as follows:

Each figure is divided into an integral number of equal-time sections and the product of the mean ordinate by the mean abscissa is obtained for each

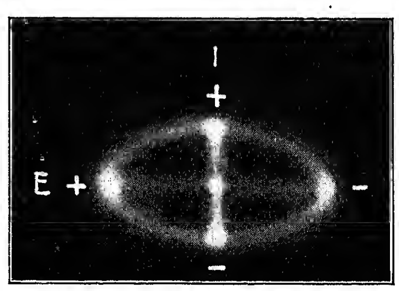

Fig. 2—Cyclogram of Capacity Current Before the Start of Corona

section. The average of all such products is then multiplied by the circuit calibration constants, volts and amperes per unit deflection of the cathode beam. The result is expressed in watts. This is equivalent to transcribing the figures to rectangular coordinates and then integrating the power wave in the usual manner. Power of the order of 0.1 watts can be measured with an accuracy of about 1.0 per cent.

The general arrangement for corona measurements is shown in Fig. 1. The measurements were usually made between a single wire and a plane. Precautions were taken to eliminate the end effect by making the measurements on about 10 ft. of wire in the central

part of the plane. Precautions were also taken to guard against stray fields and to prevent phase angle displacement errors.

Since they are very completely covered in the supplemental paper, it is not necessary to go into further details here regarding the measurements.[4]

The assistance of Messrs. W. L. Lloyd, E. C. Starr, T. M. Hotchkiss, and other members of the High Voltage Engineering Laboratory Staff in carrying on this investigation, is acknowledged. Mr. Starr's work in making the measurements was especially valuable.

Early Work and Laws for Determining Loss and Critical or Starting Voltage

The following brief statement of laws established in the first paper of the series should be of assistance in comparing the earlier work with the present.

The several laws of corona are as follows:

The *visual critical voltage* or the voltage at which corona first starts:

$$e_v = g_v\, r \log_e \frac{s}{r} \text{ kv. to neutral (crest)}$$

$$g_v = 30\,\delta\left(1 + \frac{0.3}{\sqrt{\delta\, r}}\right) \text{ kv. per cm. (crest)}$$

$$\delta = \frac{3.92\, b}{273 + t}$$

Where

r = radius in cm.,
s = spacing in cm.,
t = temp. deg. cent.,
b = barometric pressure cm.,

The power loss is:

$$p = \frac{241}{\delta}\,(f + 25)\,\sqrt{r/s}\,(e - e_0)^2\, 10^{-5} \text{ kw. per km. of one conductor}$$

$$e_0 = g_0\, m_0\, r\, \delta \log_e \frac{s}{r} \text{ effective kv. to neutral}$$

$g_0 = 21.1$ $\qquad m_0$ = irregularity factor

For small conductors:

$$e_d = g_0\,\delta\left(1 + \frac{0.30}{\sqrt{\delta r}}\left(\frac{1}{1 + 230\, r^2}\right)\right) r \log_e \frac{s}{r}$$

This has been referred to as the *quadratic law* and states that the loss increases as the square of the excess voltage above the disruptive critical voltage, e_0. The quadratic law obtains when a plot between $\sqrt{p}$ and e gives a straight line. The *disruptive critical voltage,* e_0, is lower than e_v and, in fact, corresponds to a gradient of $g_0 = 30$ kv. per cm. or the strength of air in a uniform field. In the early work it was stated that with a polished conductor, no loss would be expected below the visual critical voltage e_v. It was further stated that the loss should then start quite suddenly and follow the quadratic law. For rough conductors the loss should be expected below e_v due to the surface irregularities. This should follow because abrasions, dirt, and other chance irregularities cause high local stress and thus local corona and loss below e_v. Since local corona is caused by chance conditions, it is difficult to predetermine. It was shown that this loss followed the probability law.

Corona Loss Measurements By The Cathode Ray Oscillograph

Power Loss and the Quadratic Law. In Fig. 3A, measurements made by the cathode-ray oscillograph are plotted between loss p, and voltage e, for a small wire. The $\sqrt{p}$ is plotted with e in Fig. 3B where

the resulting straight line is the test of the quadratic. The loss starts suddenly at e_v and follows the straight line. The extension of this line cuts the axis at e_0 or e_d. Between e_0 and e_v there is very little loss for this relatively smooth wire. This curve is a check on the quadratic law for voltages up to ten times the starting voltage.

Fig. 4 shows that a larger polished wire also follows the quadratic law above e_v, or that

$$p = k\,(e - e_0)^2.$$

The Disruptive Critical Voltage and Visual Critical Voltage. The disruptive critical voltage e_d or e_0 is due to

a gradient of 30 kv. per cm. at the conductor and is the voltage used in the quadratic, for large conductors; e_d is used for small conductors. The gradient g_0 corresponds to the strength of air. Quoting from the first paper, "With perfect conductors loss does not start

at the voltage e_0, at which the disruptive gradient is reached at the conductor surface, but only after the disruptive strength of air has been exceeded over an appreciable distance from the conductor, that is, at a higher voltage e_v. With such conductors there would be no loss until e_v was reached. The loss would then suddenly take nearly the definite value calculated for this applied voltage by the equation."[3] With the usual imperfect conductors there is loss below e_v due to tufts of visual corona at local irregularities. Any appreciable corona loss is thus always accompanied by visual corona. For a dirty or mutilated wire, loss occurs at local brushes below the true e_v for the wire. These local losses below or near the critical voltage are difficult to predetermine because they are caused by

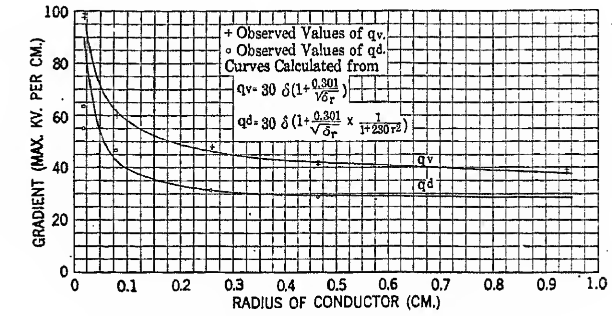

Fig. 5—Critical Disruptive Gradient

chance conditions. This is generally not of great practical importance as it is desirable to operate below e_0. The loss on new wires decreases after operation as the irregularities are burned off. The local irregularity

loss then becomes insignificant compared to those caused by dew, frost, rain, etc.

Values of g_v and g_d or g_0 determined by the cathode ray oscillograph are the plotted points in Fig. 5. The drawn curves are the calculated values. The check is very good.

Loss Near the Critical Voltage and the Effect of the Condition of the Conductor Surface. In Fig. 6, loss

curves are plotted for a rough and for a highly polished wire both directly between p and e and between $\sqrt{p}$ and e. The curve between the $\sqrt{p}$ and e shows that the loss follows the quadratic law. For the polished wire there is no loss until e_v is reached. At that voltage the loss suddenly takes a definite value on the quadratic curve. With the rough wire there is loss below e_v due to local brushes at irregularities. The loss on the rough wire is in excess of the loss on the smooth wire up to about twice e_v. As determined in the early work, this excess loss follows the probability curve

$$p = q\,\epsilon^{-h(e_0 - e)^2}$$

Fig. 7 shows loss curves near e_0 for smooth, rough, and mutilated conductors. The excess loss for the mutilated conductor is shown by the dotted line. The ratio between e_0 for the rough and polished wires gives the irregularity factor m_0. After operation or weathering, the loss at e_0 becomes quite small.

The measurements by the cathode ray oscillograph are thus quite in agreement with laws formulated in the former work as follows:[5]

a. At the visual critical voltage and above, corona loss follows the quadratic law over a wide voltage range, or

$$p = k\,(e - e_0)^2$$

b. There is no loss below e_v for polished wires.

c. For roughened wires, there is a loss below e_v at spots due to local corona. The critical voltage, e_0, is then decreased by a factor m_0. This irregularity loss follows the probability curve. For the ordinary weathered cable, the loss is generally not far from the quadratic down to e_0.

d. e_0, e_d, and e_v check former measurements.

The loss as affected by various factors will be more critically studied later in connection with the cyclograms. In the curves in Figs. 3, 4, and 6, the loss is not reduced to the equivalent of parallel wires. This can be done by a correction factor. The loss is somewhat less than that for parallel wires due to the fact that the ground plate from which current was taken was not of infinite extent. Part of the flux went to this plate and part to the equivalent of an infinite plane. The loss

may be corrected so that it corresponds to one of two parallel wires of the given length by multiplying by the proper factor.

THE MECHANISM OF CORONA OR HOW CORONA FORMS

The Critical Voltage or Breakdown. The cathode ray oscillograph gives a very good picture of the mechanism of corona formation from instant to instant during the a-c. wave. Some exceedingly interesting facts have been observed. For instance, as the applied voltage is increased above the visual critical voltage, e_v, corona starts at a lower and lower instantaneous voltage on

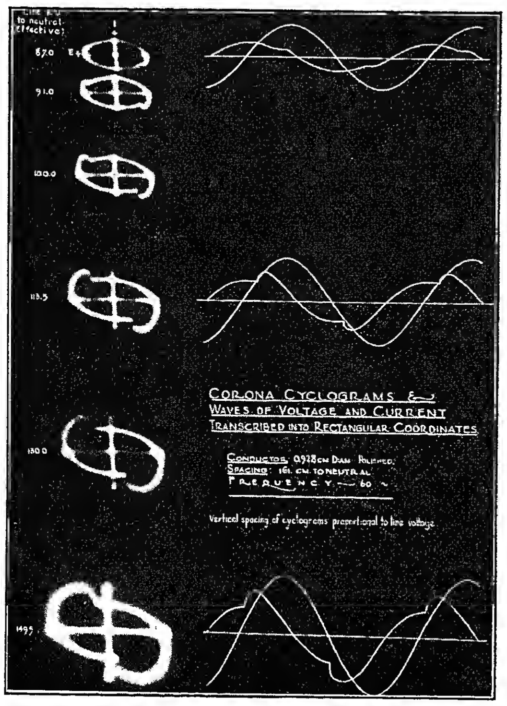

FIG. 8—VARIATION OF INSTANTANEOUS CORONA STARTING VOLTAGE WITH APPLIED VOLTAGE

Applied Voltage (kv.)		Visual critical voltage (kv.) (Max.)	Instantaneous critical voltage (e_i) (kv.)

the wave. The instantaneous value of the starting voltage on the a-c. wave actually becomes zero when the applied voltage is approximately $2e$ and finally crosses zero at higher applied voltages.

The visual critical corona voltage or the a-c. voltage at which corona starts when a low voltage is applied and gradually increased, is very sharp and definite and can be determined with accuracy. The formula for calculating this voltage is given above and seems to check well with the present tests. When the voltage is increased above the visual voltage and then reduced, the corona stops at the same voltage at which it started.

Loss occurs when the voltage is above the critical voltage. A study of the instantaneous corona at voltages in excess of the critical voltage is thus important to an understanding of the mechanism of corona loss. Fig. 8 shows a set of cyclograms taken on a wire. The top figure was made just at the start of corona at e_v, and represents capacity current with a slight corona hump at the maximum of the voltage. The ordinates give current, while the abscissas give voltage. Following the X axis to the left, it will be noted that a sudden increase of current or hump starts just before the maximum voltage is reached, and at an instantaneous voltage not far from e_v. At the maximum voltage, the corona hump disappears. The curve is then approximately the capacity ellipse, altered somewhat by

the motion of the space charge, until corona starts again on the next half-cycle. The polar diagrams have been translated to the usual rectangular co-ordinates at the right. The corona hump is well shown in these figures. It will be noted that the corona starts at a

lower instantaneous voltage as the applied increased until in the last figure the in- us starting voltage on the a-c. wave e_i is ;ro. At a still higher voltage, e_i passes ero or becomes negative, as in Fig. 9. Re- Fig. 11A, when the voltage is gradually corona starts at the maximum of the wave visual critical voltage e_v is reached. This very definite. When a higher voltage, e, as in Fig. 11B, corona starts during the first at the instantaneous voltage e_v. The charge

nductor is then q_v or the flux is ψ_v. e_v is the ecessary to produce the flux or the charge ;o cause the breakdown gradient g_v. In this · example, assume that the wire at the start e. After corona begins, the positive ions are to it and discharged. The repelled ions effect a charged cylinder, of varying diameter, ng the conductor. The stress between the · and this charged cylinder, or "space charge," ains more or less constant with increasing r just high enough to maintain the corona ircs; see Fig. 15. The stress is limited by the n gradient of the air, g_0. Corona continues to to increase the outer cylinder until the maxi- tage is reached or slightly passed, when it t this instant, the stress between the wire ;orona cylinder is just below the breakdown Vith decreasing voltage, the stress between ind the space charge decreases and somewhere scending wave becomes zero. This leaves for nt the total flux on the space charge. The · and the space charge are then at the same This occurs at $e - e_v$ on the descending ; there were no drop in the corona, this con- uld occur at the maximum of the wave. With reversal of the voltage, the space charge, in effect, adds to the charge on the conductor. When the sum of these two charges becomes, in effect, equal to q_v, so as to cause a gradient g_v near the conductor surface, breakdown occurs. Then, if the charge due to the voltage is q_i, and that due to the space charge is q_s, breakdown occurs when

$$q_i + q_s = q_v$$

or in terms of flux

$$\psi_i + \psi_s = \psi_v$$

In Fig. 11B, the voltage has been increased above e_v. It is seen that corona starts at the reduced instantaneous voltage e_i on the second or + half-cycle. This is the voltage necessary to produce the flux ψ_i. The effect is as if the charge q_s produced by the excess in the voltage above e_v on the first half-cycle were added directly to the charge on the conductor in the next half-cycle so that corona starts when the sum of these becomes q_v. In other words, corona starts at the instantaneous voltage e_v on the first half-cycle that the voltage is applied. On the next and following half-cycle it starts on the wave at a lower instantaneous voltage, e_i. Fig. 12 shows this graphically.

In Fig. 12A, flux just sufficient to start corona at voltage e_v is shown leaving the conductor. Corona "arcs" are about to form, suddenly increasing the voltage across increased capacity and causing the sudden increase in current shown in Fig. 9. Fig. 12B shows the conditions at the maximum of the voltage wave. The outer cylinder has been charged through the corona "arcs." The stress at the conductor is still sufficient to maintain corona and there is considerable

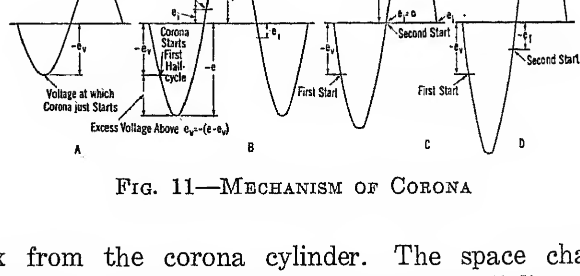

FIG. 11—MECHANISM OF CORONA

flux from the corona cylinder. The space charge cylinder has been fully charged and the "arcs" die out as the voltage starts to fall. Fig. 12C shows the point on the decreasing wave where all the flux is on the space charge and there is no voltage between the conductor and the space charge. In Fig. 12D, corona is starting on the second half-cycle at the reduced voltage e_i. The same flux is attached to the conductor as caused by the voltage e_v, in Fig. 12A. The flux is caused partly by ei and partly by the space charge. It is thus not necessary for e_i to be as great as e_v to cause the breakdown gradient.

The reduction in instantaneous critical voltages is approximately equal to the excess of the applied

voltage above e_v. Thus, if e is the applied voltage,

$$e - e_v \cong e_v - e_i$$

or

$$e_i = 2e_v - e.$$

This equation states that the instantaneous starting voltage, e_i, is zero when the applied voltage is $2e_v$, or that when the space charge is in effect q_v, no additional charge is needed to start corona. Instantaneous voltages, e_i, are plotted with applied voltages in Fig. 13. Note that e_i is zero at approximately $2e_v$.

Center figures. Schematic diagram of corona discharge circuit

If the above rule held over a wide range of voltage, it would be found that

$$e + e_i = 2e_v = \text{constant}$$

As a matter of fact, as would be expected, the tests show that $e + e_i$ is not constant, but approximately so, near the critical voltage. Actually, the effect is as if the total space charge were not effective in reducing the critical voltage, but that

$$e_i = e_v - (e - e_v)\, a$$

where a is a leakage factor and is less than unity. Fig. 14 shows this for several different wires. If the total charge were effective, the curves would be parallel to the x axis. At 420 cycles, as would be expected, the leakage is not appreciable.

It is stated above that the stress at the conductor after corona starts does not increase with increasing voltage but remains at a value just sufficient to keep the air broken down and to supply the outer cylinder or

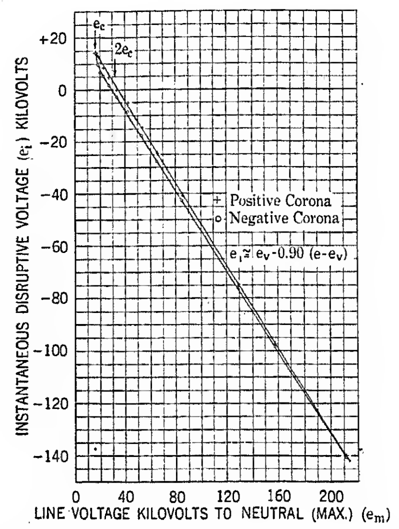

FIG. 13—VARIATION OF INSTANTANEOUS VOLTAGE OF CORONA FORMATION WITH LINE VOLTAGE

Conductor: Solid-smooth surface. 0.015 in. diameter
Spacing to neutral: 63.5 in.

space charge. This is illustrated by the test curves in Fig. 15. The voltage was measured between the conductor and small wires placed at different points in space. It will be noted that the voltage between these points increases directly with increasing voltage until the critical voltage is reached, after which the voltage remains more or less constant.

Artificial Corona. The mechanism of the corona breakdown can be illustrated with condensers. For the sake of simplicity, take two condensers as in Fig. 16. Shunt one of these with a gap set to spark at voltage e_1 and of such characteristics that it never short-circuits c_1. This gap thus has a valve action sparking when a voltage e_1 is impressed across it but not short-circuiting c_1. On the first half-cycle, the spark, which represents

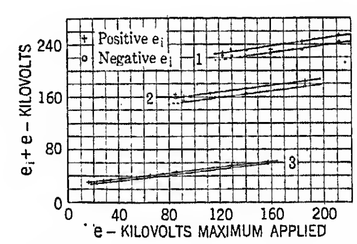

FIG. 14—VARIATION OF $e_i + e$ WITH LINE VOLTAGE

Spacing: 161. cm. to neutral

the corona, starts at the instantaneous line voltage e_v, because e_v is the total applied voltage that causes the breakdown voltage e_1 on c_1. At that instant the voltage across c_2 is $e_v - e_1$. With increasing line voltage, the voltage across c_1 does not rise above e_1 because of the arc. The excess voltage is placed across c_2. When the maximum of the wave is reached, the current stops and the arc goes out. At a voltage $e - e_v$ on the falling quarter of the wave, the total voltage is on c_2. Finally, on the + half of the wave, the voltage across the gap again becomes e_1 and the spark again starts. This occurs at the instantaneous line voltage e_i. e_i is lower than the instantaneous voltage e_v at which corona started on the first half-wave, by the amount that e exceeded e_v because an excess charge, $(e - e_v)\,c$, on c_1, adds to the charge due to the line voltage, or

$$e - e_v = e_v - e_i$$
$$e_i = 2e_v - e$$

This is the relation arrived at for corona on wires and, as in the case of corona, the spark starts at zero instantaneous line voltage when the applied voltage is twice the critical voltage. The above holds whatever the relation between the capacities of the condensers, or whether one gap is used or several gaps are used to break down successively. The actual corona loss relation would be more nearly approached with a successive breakdown of gaps with increasing voltage.

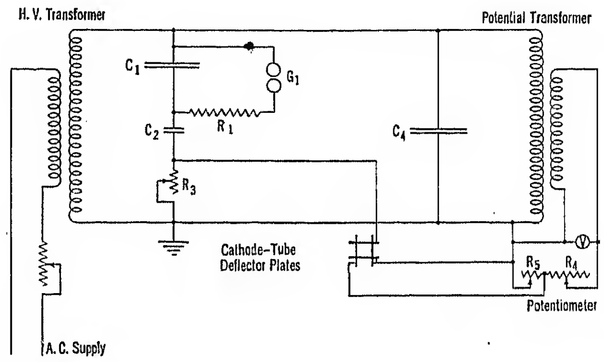

Fig. 17—Single-Gap Circuit for Producing and Studying Artificial Corona

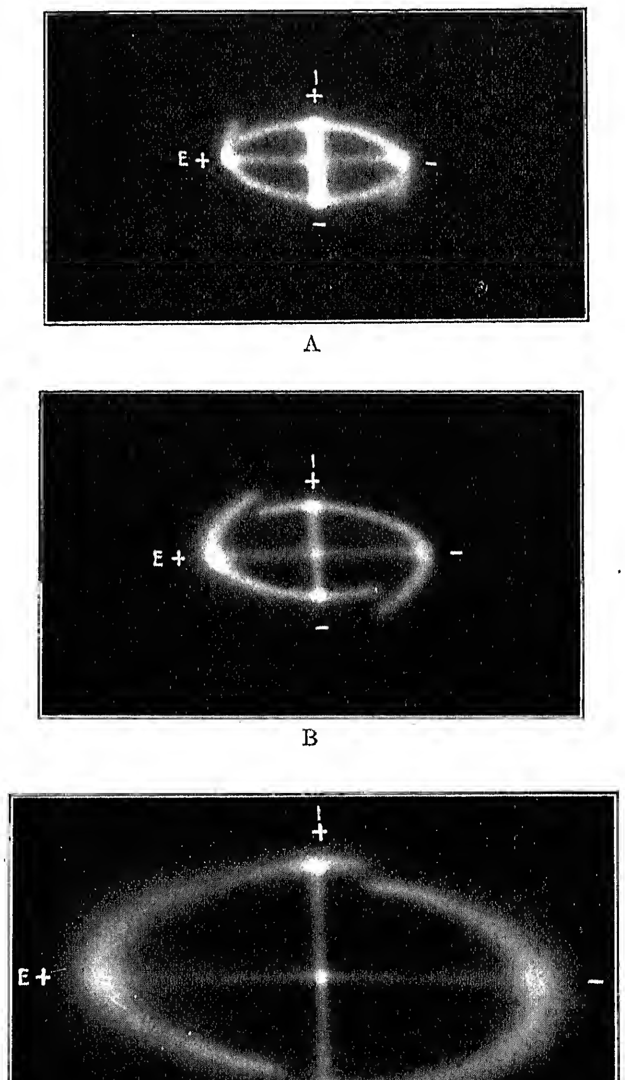

Fig. 18—Artificial Corona

A—Just above critical voltage
B—Considerably above critical voltage
C—Over twice critical voltage—corona starting "below zero"

A similar voltage relation holds if the gap is permitted to short-circuit the condenser except that the gap must then be set at double voltage. The voltage relations are followed out for several half-cycles in Fig. 16. The arrows on the condensers show the relation of the fluxes at different parts of the wave. In one instance it will be noted that all of the flux is attached to the "space charge" or condenser c_2.

Compare Fig. 16 with Fig. 12, where the same relations are shown for actual corona and space charge.

A condenser arrangement for artificial corona was made as in Fig. 17. Tests were also made with several gaps breaking down successively. The cyclograms in Fig. 18 show how closely artificial corona agrees with actual corona.

The Power Loss. The mechanism has so far been described up to the point where the charge of the ionized space of the first half-cycle in effect adds to the charge on the conductor of the next half-cycle and breakdown occurs when the sum of these two charges is in effect equal to q_v, or causes a stress g_v. In this particular case, the start was made with the wire (−). The returning charge was then also (−). Following the new break, this was cancelled by a (+) charge while a (+) charge was repelled from the conductor. The space charge cylinder moves out with increasing voltage and is charged through the corona arcs until the wave reaches maximum. The arcs then die out or corona stops. The sudden increase of current at the critical voltage is

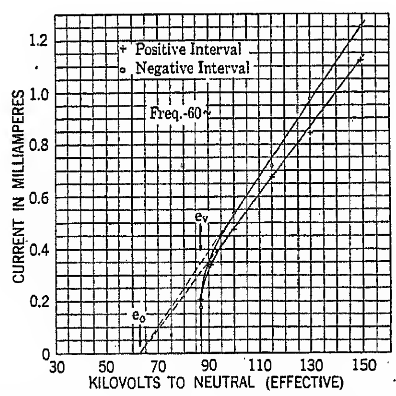

Fig. 19—Effective Corona Current During Disruptive Interval

Conductor: 0.927 cm. diameter, polished
Spacing to neutral: 161. cm.
Length: 305. cm.

caused by a sudden increase of voltage across the increased capacity. Part of the energy in the "space charge" field is returned to the circuit and part of the energy is not returned or is returned at the wrong part of the wave and is lost. When the conductors are far apart, the main part of the loss occurs in the space between the conductor and corona cylinder. Where the conductors are close together, or the voltage is approaching the spark-over voltage, a conduction loss is also caused by ions migrating to the opposite conductor. The measurements show that over a very wide range of conditions the loss follows the quadratic law

$$p = k_1(e - e_0)^2$$

An examination of the mechanism makes this appear the rational form for the loss to take. This seems so for the following reasons: The space charge is proportional to $(e - e_0)\,C$. Energy is required to move this charge through the field or through the voltage from the conductor to the corona cylinder. The voltage between the conductor and the space charge or corona

*In making the loss calculations, the values of C in the formula were corrected to correspond to the actual capacitances of the conductor to the active section of the ground plate. The factors were determined by comparing the calculated and measured charging currents.

The measured values are the actual values computed from the cyclograms.

* * * * * * *

The check between the measured values of loss and the corresponding values calculated by the above simple formula is very good when s/r is large or when the frequency is high. When s/r is small or when the frequency is low, it is necessary to introduce a factor which is a function of the capacitance and also a factor to take care of ionic leakage as in the quadratic law. Thus in the tables above, for the lower values of S/r with 60 cycles, the difference between the measured and calculated watts is considerable. The corrective factor has not been applied to any of the above tables.

cylinder is proportional to $(e - e_0)$ and, in fact, appears to equal $(e - e_0)$ for the higher frequencies and very large spacings. The energy may be considered as being lost in the resistance of the corona arcs charging and discharging the corona cylinder. The loss is thus

$$w = (e - e_0)\ (e - e_0)\ k\,C = (e - e_0)^2\,k\,C$$

or the power

$$p = 4\,f\,C\,k\,(e - e_0)^2$$

The above relation checks the measured values for

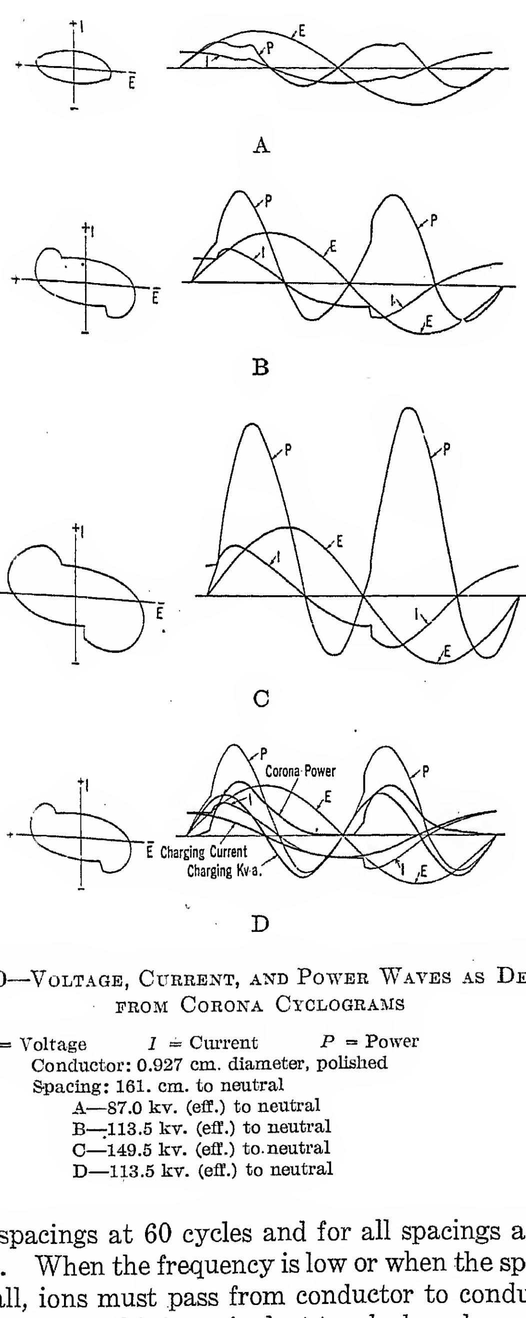

FIG. 20—VOLTAGE, CURRENT, AND POWER WAVES AS DERIVED FROM CORONA CYCLOGRAMS

large spacings at 60 cycles and for all spacings at 420 cycles. When the frequency is low or when the spacing is small, ions must pass from conductor to conductor; see Table V. This is equivalent to a leakage loss or loss in a resistance intermittently placed from conductor to conductor. Then

$$p = k_2\,(f + a)\ C\ (e - e_0)^2$$

wherein the factors a and k are an integral part of the equation and were originally determined empirically in the quadratic law. The part of the energy in the space charge that is returned to the circuit at the proper part of the wave is not lost but gives the extra capacity effect of corona.

There is no loss at e_0 because breakdown does not take place until the voltage e_v is reached. There is then a sudden break over a finite distance from the con-

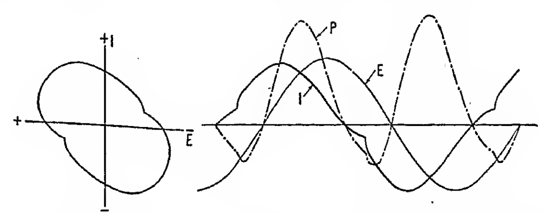

FIG. 21—WAVES OF VOLTAGE, CURRENT, AND POWER—VOLTAGE FAR IN EXCESS OF CRITICAL VALUE AS DERIVED FROM CORONA CYCLOGRAMS

e_i = 9.5 kv.

ductor and the loss falls on the quadratic curve with e_0 as the disruptive critical voltage. The stress between the conductor and the corona cylinder is not reduced to zero when corona starts but has a value approximately equal to g_0 or g_d at the conductor and decreases outward to the corona cylinder along approximately the same curve that obtained just before corona started. Beyond the corona cylinder, the average stress must be higher or the curve flatter to maintain the voltage proportional to e_0 across the portion that is not ionized.

It might be expected at first glance that the disruptive critical voltage should be e_v rather than e_0, since loss does not start on polished conductors until e_v is reached. A more critical examination, however, shows that following the initial break controlled by g_v, the strength of air becomes g_0. Thus, although g_v controls the start of the loss, after the initial break occurs and corona extends out, the controlling gradient is g_0. This

follows up to the maximum of the voltage wave when corona stops. g_v is required to cause the next start, etc.

It is interesting that when the applied voltage is zero, all of the energy is on the space charge and is

$$(e - e_v)^2\ \frac{C\,C_2}{2\,C_1}$$

The voltage, current, and power relations are shown very well for a polished conductor 0.365 in. in diameter at different voltages, in Fig. 20. The relations are shown in rectangular coordinates transcribed from the

measured cyclogram at the left of each figure. Fig. 20A was taken near the critical voltage. The (+) and (−) power waves are practically equal and correspond to the charging kilovolt-amperes except for the excess (+) hump caused by the loss. In Fig. 20B, the voltage has been greatly increased and the instantaneous starting voltage e_i has decreased. There is now a considerable excess (+) power, but without the decided hump. In Fig. 20C, the voltage has been increased to almost 2 e_v. e_i has approached zero. The power wave is now smooth.

Fig. 20D is the same as 20B with the addition of the charging kilovolt-ampere curve and the difference between this curve and the total power curve. This is the approximate corona loss curve.

An examination of the current curves in Fig. 20 shows that for a polished wire the instantaneous corona start is extremely rapid on the negative half of the wave, while on the positive half it is more gradual. The start on the negative half is so rapid that oscillations are readily produced. The effect of the conductor surface is shown very well in Fig. 10. A cable acts very much like a dirty wire.

An examination of the power curves shows a difference for (−) and (+) corona. There is not, however, any great difference in the actual loss on the different half-cycles.

Figs. 13 and 14 show a slight difference in the instantaneous starting voltages.

Fig. 21 is interesting. It was taken at a voltage considerably higher than the critical voltage, e_v. The instantaneous e_i voltage has decreased below zero or the *corona starts on the falling wave.*

Fig. 22 shows corona at 420 cycles. The characteristics are the same as at 60 cycles except that there is less evidence of conduction as would be expected.

Fig. 23 shows that the corona at 420 cycles follows the quadratic law.

Characteristic voltage, current, and loss curves for artificial corona are given in Fig. 24.

Discussion

AN INVESTIGATION OF CORONA LOSS
(Starr and Lloyd)

LAW OF CORONA AND DIELECTRIC STRENGTH
(Peek)

Detroit, Mich., June 24, 1927.

V. Karapetoff: The diagram of connections used by the authors permits of obtaining an oscillogram of the total current, consisting of a reactive charging component and an in-phase energy component. In some cases it may be of interest to obtain a picture of the latter component alone. Perhaps this could be accomplished by some differential arrangement; that is, by using a condenser which takes the same reactive charging current as the conductor under test but has practically no corona loss. The high-voltage side of the step-up transformer would then be wound for a double voltage, with the middle point grounded; the added condenser would be connected to the other terminal of the transformer, and the resistance R_3 would be connected to the neutral point. Only the difference of the currents taken by the conductor under test and the perfect condenser would flow through R_3.

A Mechanical Transcriber. With an increasing use of the cathode ray oscillograph in practical work, the problem of rapidly transcribing records with a sine-law axis of abscissas to those with

Cartesian coordinates becomes one of considerable importance. Where hundreds of similar records have to be transcribed, the tedious point-by-point method of transfer of individual ordinates can hardly be considered satisfactory. A mechanical transcriber is a device consisting of kinematic connections with a stylus at one end and a pencil at the other. By going with the stylus over the outline of an oscillogram on a photographic film, the pencil is made to draw on a strip of paper the corresponding curve in rectangular coordinates.

In order to enable those interested to build a mechanical transcriber, the underlying principle is shown in Fig. 1 herewith. The film containing the record is fastened to the platen 2-2, which has a slot, 3. A pin, 4, attached to the crank, 5, can slide in the slot. When the crank is turned by means of the handle, 6, the platen and the oscillogram perform a harmonic motion along the X-axis. The same crank, through the friction wheel, 7, drives the table 8-8, to the left. A strip of paper is fastened to this table, and the pencil, 15, draws a curve in Cartesian coordinates. It will be seen that by means of this mechanism the sine-law abscissas are wiped out, and abscissas proportional to time are substituted.

To transfer ordinates of the oscillogram from the platen to the table, the carriage 9-9, with a crossbar, 10, is used. The carriage can be moved up and down on the rails 12 and 13. The pencil, 15, is attached to the carriage by means of the bracket 14. The stylus, 11, is fastened to the crossbar, 10.

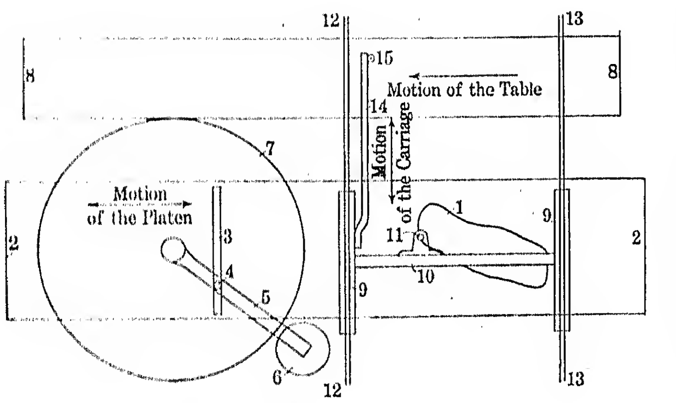

FIG. 1

To operate the transcriber, the crank is turned slowly and at the same time the carriage is moved up and down in such a way that the stylus always remains on the curve. The pencil then traces the transformed curve. When many oscillograms are to be transcribed, one person should turn the crank and another operate the carriage.

Determination of Power Loss by Weighing. When power loss is to be evaluated regularly from a large number of oscillograms, the point-by-point method described in the paper may prove to be too tedious. It is necessary to measure a large number of ordinates, multiply each by the sine of an angle, and add the products, keeping the positive and the negative quantities separate. An automatic method of weighing may prove useful in such cases, especially since it enables us to use a much larger number of ordinates with a comparatively small additional required amount of time. The principle of the method is shown in Figs. 2 and 3. For the sake of illustration, we shall assume, with the authors, that it is sufficient to divide each cycle into 20 equal intervals of time, Δt, each corresponding to 18 electrical degrees. Replacing integration approximately by summation, the average power, P, per cycle may be written in the form

$$P = (1/T) \sum_{t=0}^{t=T} i_m \, e_m \, \Delta t$$

where T is the duration of a cycle, and i_m and e_m are the average values of current and voltage during the small interval Δt. In Fig. 2, the curve, $a\ b\ c\ d\ f\ h$, represents a loop obtained experimentally, with sine-law abscissas. The circle, N is drawn with a radius equal to the amplitude of the voltage, $E = O\,g = O\,k$. The circle is divided into 40 equal parts, corresponding to 9 deg. each. Thus, the arc p corresponds to the interval Δt, and r is the middle point of this interval. $O\,s$ is the mean voltage e_m during this interval, and $s\,v$ is the corresponding

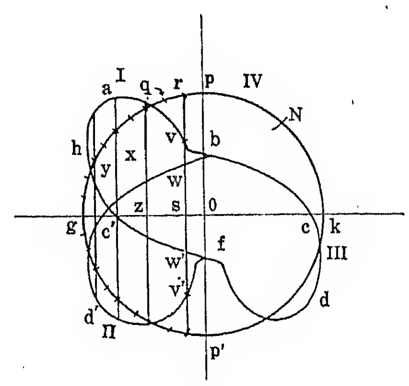

FIG. 2

mean current, i_m. Similarly, the ordinates x, y, etc., mark the middle points of the consecutive intervals Δt. The abscissa $O\,s = E \sin 9$ deg., the next abscissa $O\,z = E \sin 27$ deg., etc. Thus, eq. (1) becomes

$$P = (\Delta t/T)\ E\ [i_{m1} \sin 9^\circ + i_{m2} \sin 27^\circ + \text{etc.}] \qquad (2)$$

Instead of scaling off the ordinates and multiplying them by the sines of the corresponding angles, the simple balance beam, shown in Fig. 3, may be used. It is provided with notches at distances from the center proportional to sin 9 deg., sin 27 deg., etc. The beam is supported in the usual way on a knife edge at the center, has a pan P at one end and a counterweight, Q, at the other end, to balance the pan. Some strip or wire of uniform weight per unit length is provided, so that lengths can be measured by weighing. Let a piece of length, $s\,v$, be cut off

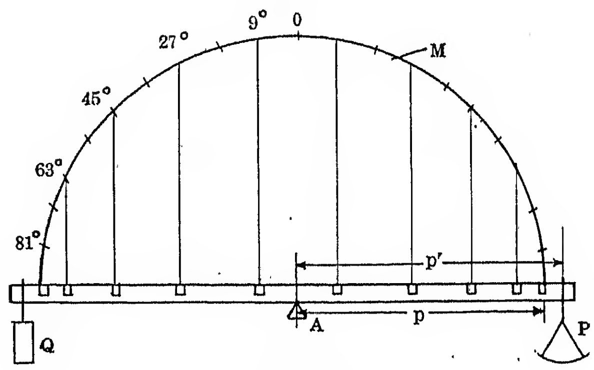

FIG. 3

and placed in the first notch to the left of A. The turning moment exerted upon the beam will be proportional to i_{m1} sin 9 deg., that is, proportional to the first term within the brackets in eq. (2).

Corresponding strips are placed in the remaining notches. The ordinates in the quadrants I and III of the loop give positive values o' torque (counter-clockwise), and those in quadrants II and IV contribute to the negative torque. Having placed all the strips, the beam is balanced by putting some strip in the pan P. Let the length of this strip be l. If the pan were placed at the distance p from A, corresponding to the radius of the semi-

circle M, the length I would represent the value of the expression in the brackets. If the pan is at a distance p^1, the corrected value of I, reduced to the arm length p, is $I\ (p^1/p)$. All the quantities in eq. (2) being known, the power P may be readily computed.

The number of strips may be reduced to one-half by re-drawing the parts of the loop in the quadrants III and IV in quadrants I and II, as shown by the curve $b\ c^1\ d^1\ f$. This can be easily done by folding the film along $p\ p^1$. In this case, instead of cutting a piece of strip equal to $s\ v$, and later one corresponding to $s\ v^1$, a piece of length $v\ v^1$ can be cut off at once, covering both positive quadrants I and III. Similarly, a piece of length $w\ w^1$ will take care of both negative quadrants. Since both strips act on equal lever arms, the net results on the beam is the same as if piece of lengths $v\ w^1$ and $w^1\ v^1$ were placed on the positive side. This procedure of using different pieces on the beam may be used, if it appears to be preferable.

Other Uses of Weighing. A similar method of computation by weighing may be used in other cases when the unknown quantity is of the form

$$Q = a\,x + b\,y + c\,z + \text{etc.} \qquad (3)$$

wherein a, b, c, etc., are known constant coefficients, and x, y, z, etc., are some measured quantities. In a balance beam, notches are then made at distances a, b, c, etc. (positive or negative) from the knife-edge support, and strips of paper or metal, or wires of lengths x, y, z, etc., are placed at these lever arms, keeping in mind the sign of each product. The length of wire or strip necessary to balance the beam, multiplied by its distance from the center, will give the value of Q in eq. (3). The following examples may be cited:

(a) In cost estimates, where a, b, c, are unit costs and x, y, z, are quantities of materials,

(b) In computing the voltage drop along a line with branch loads.

The factors a, b, c, may then represent lengths and x, y, z, load currents.[1]

(c) When analyzing an irregular wave into its harmonics, equidistant ordinates are multiplied by the sines of certain angles.[2] By providing a balance somewhat like in Fig. 2, and another with cosine notches, the amplitudes of harmonics can be quickly and accurately determined. Two balance beams are necessary for each harmonic, so that the arrangement would pay only when a large number of waves is to be analyzed.

C. F. Harding: Referring particularly to the reference to the loss due to corona, it may be well to point out that these papers confirm the importance of attacking a problem such as this from many different angles, in many different sections of the country, and on many different transmission lines.

Beginning about the year 1912, and extending through several papers before the Institute, and a number of discussions, results of net losses due to corona on various transmission and experimental lines have been presented by various authors, and compared with the theoretical values, *i. e.*, the empirical equations which have been developed in various laboratories.

In most instances, those losses have compared favorably with the results calculated from the formulas which have been developed by Mr. Peek, and which have been repeated in this paper. That is particularly true for the losses at relatively low voltages, such as those up to and slightly exceeding the critical voltage between wires. If the net loss due to corona calculated by Peek's formula be plotted in kw. as ordinates, and the kilovolts between cables or between one cable and neutral be expressed as abscissas, a parabola results as indicated in the paper. If the actual net loss due to corona be plotted for an experimental line or for a transmission line operating under the same conditions, *i. e.*, the same frequency, density factor, size cables, spacing, etc., this curve checks very closely at low voltages with the quadratic curve. In many instances the test curve was found to be slightly higher in the lower range of voltage, but had considerably lower values of power loss throughout the higher ranges of voltage.

In other words, if we assume that the net corona loss in kw. is equal to some constant multiplied by the square of the difference between impressed voltage and critical voltage, the quadratic law of Peek's formula results. Actual tests show a curve of smaller loss and less slope at the higher voltages; at least on the lines at Purdue University. This would seem to indicate that either this exponent (2) is a little high, or that the critical voltage E_o varies with the voltage E impressed upon the line. Possibly both conditions exist simultaneously. Actual values for the exponent—call this N—have been of the order of 1.55 to 1.7 but always less than the 2 of the quadratic law of Peek.

In the paper presented by the speaker in 1924 at the Pasadena convention, the result of the possible increase of this E_o, *i. e.*, the disruptive voltage of air, because of the formation of the coronal cylinder of greater capacitance, at these higher values of voltage, was suggested. If we consider that this relatively large conducting cylinder of ionized air which has been termed the coronal cylinder does exist about the cable at extra high voltages, in other words, if we take the assumption of the papers presented by Messrs. Peek, Lloyd, and Starr, it is probable that the critical voltage E_o at this point, as the result of the larger capacitance of this larger coronal cylinder, does change materially with these very high voltages impressed between cables. We are dealing with the critical voltage at the surface of the coronal cylinder or some other intermediate point rather than the voltage at the cable itself.

This would seem to indicate that it may be possible, by means of tests on transmission lines where net losses due to corona are determined very accurately from wattmeter measurement in the high-voltage circuit itself, to bring these test relations into conformity with, or conversely, and more appropriately to bring the formula into conformity with the empirical functions established by such tests.

The important feature of this, it seems to me, is the fact that in practically all these tests, made over a long series of years, including a large number of spacings of cables ranging from 18 ft. to 38 ft., with sizes of cables from No. 0 up to 300,000 cir. mils stranded, that the Peek formula is a very conservative one, and that the corona loss actually is considerably less, at these higher voltages, than would be indicated by the calculations. We are on the safe side, therefore, if we design transmission lines in accordance with that formula.

The statement is made, however, in the papers under discussion that the line should not be operated at or above the critical voltage at which corona forms; *i. e.*, under dry-weather conditions. Designing for that voltage means that such a line will operate in many cases with considerable corona formation upon it, as many have noted substations and lines in more or less continuous operation with corona formation. It is important, therefore, to determine both by tests in laboratory and on operating lines just what this difference is between the two curves at the voltages in excess of the critical voltage.

W. F. Davidson: Mr. Lloyd and Mr. Starr described the method they have been using with the cathode ray oscillograph for studying corona formation. A short time ago I tried a similar tube in studying the distortion of current through a cable sample, with the idea of determining whether there was corona formation.

We used basically somewhat the ideas suggested by Professor

1. V. Karapetoff, Engineering Mathematics (Wileys), Part V, Chapter II. In the early days of electrical engineering, a German firm used to market a simple balance on which one could "hang amperes" at proper distances and balance them by a weight in the pan. The weights were stamped directly in square millimeters, to indicate the required cross-section of line conductor.

2. V. Karapetoff, Experimental Electrical Engineering, Vol. II, Third Edition, p. 577.

Karapetoff of eliminating the straight capacity component of the charging current through the samples.

The supply transformer in this case was grounded at one end; the sample S connected as indicated in the accompanying Fig. 4 and brought down through a small resistance to ground, the no-loss air condenser C connected in parallel through a corresponding resistance, in fact, two resistances. The cathode ray is connected with one plate so as to take the drop $V_s - V_c$ giving a deflection proportional to watt-component current through the sample in the test, now, by controlling the total resistance R we had the possibility of shifting the base position of the current through the air condenser. That was sometimes of value and of help.

The other component was obtained in two different ways, in the first work, much as Mr. Lloyd has described, by taking the potential applied to the transformer. We found considerable difficulty in using our particular tube, however, because neither axis was straight; that is, the pattern instead of being straight, gave two rather distorted curves.

In order to overcome that difficulty, we made a calibration in the direction of abscissa, corresponding to these deflections, then we arranged our time curve. These were controlled by a phase shifter P, that was supplied from the same primary as the transformer. The cyclogram would then appear in various forms, and we would shift the thing around, changing the phase

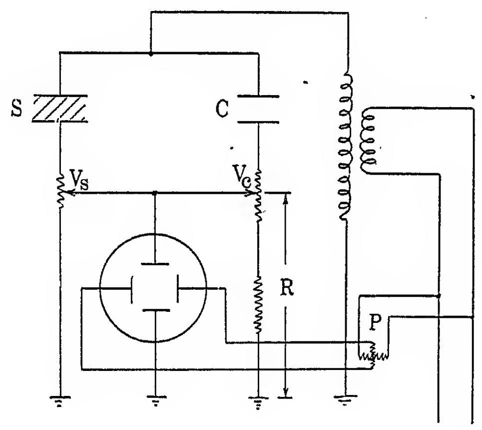

Fig. 4

around, changing the phase shifter until the particular point we were interested in was on the central axis and then we scaled this point.

There were two operators, one reading the phase shifts and the other reading the ordinates, and it took only about a minute to get a complete record. We were rather disappointed in some of the results because although they were very satisfactory in a qualitative way, we were not successful in getting them in a quantitative way. Perhaps we could do better with a tube that did not have such a badly distorted pattern.

J. Ryan: (communicated after adjournment) The results obtained by the authors of these corona papers and their corresponding conclusions will help greatly to establish a better understanding of the nature of corona. During the past four years by independent effort we have arrived at substantially the same results and corresponding conclusions. Our studies during the past year were mostly concerned with the mobility and make-up of the space charge and the manner in which its portions having constant and alternating polarities function.

Three methods have been used successfully for the cyclic study of corona by means of the cathode ray tube. In the first of these the ray-pointer is deflected electromagnetically.[3,4] In the second the deflections are produced electrostatically so as to yield quadrature ray-pointer deflections proportional to the voltage and to the rate of increase or decrease of the current in instantaneous relation. Thus the ray-pointer develops areas proportional to the time-integral of the volt-amperes or energy.[5] The third has been used by Mr. Peek and his co-workers. In it the ray-pointer is also actuated electrostatically and yields deflections proportional to simultaneous values of voltage and current. The first and third methods produce volt-ampere cyclograms and the second energy cyclograms.

The first avoids the necessity of using electrostatic deflectors mounted within the cathode ray tubes but requires a great variety of deflector current coils and potential-circuit resistors, some of which are expensive. Electrostatic deflectors mounted within the cathode ray tube are used in the second and third methods. Externally mounted electrostatic deflectors are not satisfactory because of the bound charges that assemble on the inner walls of the tube opposite the deflectors. We have used the three methods and recommend the use of the second and third. The choice depends upon the character of work to be done. Occasionally both are required in the same undertaking. Because a condenser must be used in the current circuit of the energy cyclograph it cannot be used when more than a mere trace of rectified current is present. Such current when small enough may be successfully bypassed with a "leak" of the proper value. Again when the observation of sudden changes of current or e. m. f. are to be made the energy cyclograph being a volt-ampere-time integrator, is less helpful and the electrostatically operated voltage-current cyclograph should then be used.

Following the recognition of the presence of the space charge that surrounds a conductor in corona it was found that the corona loss equals the energy that is dissipated in the space-charge condenser at unity power factor subjected to the voltage in excess of the critical voltage, *i. e.*, voltage above the lowest voltage that will sustain a fixed brush pattern.[6] Thereafter the capacitance and position of the space-charge condenser were studied with the energy cyclograph, using cylindrical barriers around the conductor to fix the radius within which the space charge is confined.[7] These studies were then followed by others to determine the central radial position of the alternating portion of the space charge by means of the potential exploring wire.[8]

During the past year my co-workers, J. C. Carroll and J. T. Lusignan, Jr., have studied the cyclic character of the ion-content of the space charge. One of the many purposes of the study was to add to the background of knowledge required to improve interpretation of the observations made with the potential exploration wire and to understand the function of the constant-polarity portion of the space-charge function in alternating corona formation. The corresponding results and conclusions are being embodied in a paper soon to be presented to the Institute.[9]

It has long since been known that the values of positive and negative corona-forming voltages differ. Dependent upon the particular conditions the difference varies from zero to a considerable fraction of either polarity of the critical voltage. The rectified portion of the space charge in alternating corona is caused by this difference. For example if the critical voltage is

greater when negative than when positive, the magnitudes of the corresponding space charges will have to be in reciprocal relation. When the conductor requires a higher negative than positive corona-forming voltage there will be formed and maintained the larger space charge from the positive to the negative voltage crests; and correspondingly the smaller space charge from the negative to the positive voltage crests. This gives rise to the phenomenon of "rectification" that is often witnessed in the study of corona. The portion of the space charge having constant polarity will increase the strength of the field attached to the conductor as the voltage approaches one crest and will d minish it as the voltage approaches the other crest. Thus the differences of the positive and negative critical fields and their corresponding initial voltages from their averages are compensated for by the presence of the constant-polarity portion of the space charge. It follows, therefore, that the initial value of the cyclic critical voltage must be as much below the value of the crest voltage as it is above the value of the subsequent critical voltage that starts corona formation in the succeeding cycles and that the positive and negative critical voltages must be equal. From the nature of things here set forth power-transmission conductors operated in corona will display constant polarity high potential phenomena to a limited extent and the direct currents thus set up in ionic mobility from the conductors through the air and over the insulators to earth are not likely to develop effects of much practical importance.

The model of corona given by Mr. Peek is helpful for gaining an understanding of the essential features of corona. The theory of this model as developed in our studies was given by Messrs. Hesselmeyer and Kostko in connection with Fig. 14 of their paper on the Nature of Corona.[8] Guided by this theory we made up in the summer of 1926 a model such as described by Mr. Peek, using a pair of Leyden jars with a spark-gap in parallel with one of them. It produced artificial corona cyclograms quite like cyclogram No. 4 in Fig. 6 of the Hesselmeyer-Kostko paper. It gave the oblique straight sided parallelograms that theory called for. Of course it did not repeat the minor departures that are witnessed in actual corona wherein the space charges are mobile. See for example the group of cyclograms in Fig. 10 of the same paper taken from a single-phase line mounted in the open to which corona forming voltage was applied.

All in this group conform liberally but not exactly to the oblique parallelogram wherein the slopes of the sides and ends determine the values of the capacitances of the conductors and space charges, and wherein the departures from the straight sided oblique parallelograms are measures of the effects due to causes that are not included, necessarily so, in the incomplete theory, such as conduction (thermal dissociation) and ionic mobility actions that Mr. Peek properly sums up in his paper by the phrase "corona arcs."

As a result of these studies we are convinced that Mr. Peek is right in his conclusion that the power-loss-voltage relation in full corona formation is a rational quadratic because of the space charge condenser. He is also right in recommending that care be used to avoid mechanical injury to the surface of the conductor. One should note, however, that losses due to local corona are greatly dependent upon the uniformity of the physical-chemical regularity. Greatest regularity is required to produce minimum local corona loss, since the maintenance of a smooth, polished conductor is not feasible. We have found this to be so for local corona loss when the mechanical irregularities or roughness of the surface of the transmission conductor have been carefully avoided. The local corona losses are likewise dependent to important extents upon the humidity in the air and the crest and effective values of the voltages. Because of the prominent part that the space charge condenser takes in corona formation one must expect the cyclic loss to be dependent upon the crest value of the voltage; again because the space charge is mobile its containing condensers do not have fixed value, and one must expect the cyclic loss to be dependent also upon the effective value of the voltage.

The local corona studies here referred to were made by our graduate students Messrs. Drodjin and Wiedeman and will be embodied in a paper that they will offer for publication at an early date. Local coronas are simply scattered brushes. In the local corona loss-voltage relation the numbers and positions of the brushes are large factors, which in turn depend upon the smaller factors just specified all of which in the full corona loss-voltage relation are of little or no importance. Local corona is an instability complex and much systematic study under all relevant conditions will have to be promulgated to know what high-voltage conductor diameters, and insulator hardware forms to adopt to meet all requirements.

E. C. Starr: Professor Karapetoff and Mr. Davidson have spoken of neutralizing the charging component of the current wave. We considered that, inasmuch as the portion of the figure that is said to represent charging current is not, strictly speaking, only charging current as based upon the capacitance of the wire itself, but charging current based upon the capacitance of the wire as affected by the motion of the space charge, we thought it best to leave it all in to show the whole wave. That suggestion, however, would allow us to show only what the corona does and under certain conditions would be useful.

Mr. Davidson spoke of his tube giving axes that were crooked. We found that the condition would be brought about if the source of the magnetic field used to neutralize the effects of the earth's magnetic field was placed too near the tube. It is necessary to place the source at a distance of 3 or 4 ft. from the tube in order to obtain a uniform field throughout the tube and thus eliminate distortion of the axes. It is possible that this was the source of Mr. Davidson's trouble.

Professor Karapetoff's mechanical devices are very clever, and should be useful where the work is to be done on a large scale.

F. W. Peek, Jr.: It is very difficult to estimate corona loss on practical lines with great accuracy because it is very difficult to determine the conditions along a long line; there are so many variables.

If a wire about an inch in diameter is taken and the loss is measured up to several million volts, it will be found that, at first, the quadratic law obtains up to a very high voltage. Finally, at some point the loss begins to fall below the original quadratic. It eventually follows another quadratic. The new curve, if extended, will be found to cut the axis at a new critical corona voltage. At the point where the deviation occurs, the appearance of the corona discharge changes. Great "cartwheels" form around the conductors. These cartwheels separate, act as shields, and change the whole electrostatic field. I do not think it is a practical condition because this deviation from the quadratic occurs at many times the operating voltage for the conductors. It is amazing, in fact, that any law is followed at these high voltages.

It seems to me that operation should be below the critical voltage for fair weather. It is practically impossible to eliminate all loss in wet weather. It is thus important to determine the irregularity factors for various types and sizes of weathered conductors. This offers a good field for investigation.

A Precision Measurement of Puncture Voltage

BY V. BUSH*
Fellow, A. I. E. E.

and

P. H. MOON*
Associate, A. I. E.E.

Synopsis.—*A description is given of an apparatus for the automatic determination of the dielectric strength of thin sheet insulation. The machine makes about 1000 breakdown tests in a day. Almost no attention is required, thus reducing the human element to a minimum.*

The results of over 100,000 punctures are given. An investigation of the effect of temperature indicates that none of these punctures occurred according to the thermal theories of breakdown. Tests to determine the effect of electrode area are also described. It is shown that statistical theory can be applied to the results with some success. The standard deviation of the breakdown values is a measure of the inherent variability of the material, and thus gives promise of value in the specification of insulation.

* * * * *

THE pyroelectric theory of insulation breakdown, introduced in 1922 by K. W. Wagner[1] and independently by Steinmetz and Hayden[2], gave a great impetus to the study of the failure of solid dielectrics. Several investigators, particularly Dreyfus[3], Kármán[4], and Rogowski[5], have added to the theory, while others such as Mündel[17], Rochow[18] and Gabler[19], have attempted experimental verification.

The experimental results to date are, however, meager and unsatisfactory, and constitute a serious barrier in the way of further progress. One reason is the difficulty of getting consistent values of puncture voltage. Breakdown measurements are inherently more erratic than either resistivity or dielectric loss measurements. Puncture depends evidently only on the strength of the weakest path through the dielectric, while the measurement of other quantities is more or less an integration process giving an average of all the elementary paths through the insulator. The only solution of the difficulty seems to be to take the average of a great number of readings.

It was our purpose to build an automatic machine to make these breakdown tests in large numbers under accurately controlled conditions and with the minimum of manual labor. Such an outfit was completed at the Massachusetts Institute of Technology in the fall of 1925†. In the school year of 1925-26, 130 runs were made with a total of over 100,000 readings.

The apparatus will test any thin sheet material obtainable in long strips. A piece 1¼ in. wide and about 80 ft. long is sufficient for a day's run of 1000 punctures. The outfit consists essentially of a pair of electrodes, an insulation feed mechanism, and suitable means of automatically raising the voltage and recording the value at which breakdown occurs. The feed mechanism operates after each puncture, bringing a fresh length of insulation between the electrodes. A 4000-volt, d-c. generator is used for the tests, the voltage being raised at a constant rate by a motor-driven rheostat in the field circuit. The value at which puncture occurs is recorded by an ordinary graphic voltmeter.

That accurate results are obtainable is shown by the results of 16,000 punctures made on thin condenser paper, Fig. 12. The probable error of the daily average is 3.6 volts. Therefore, it may be said that with this material under the condition of the tests, *the daily average is correct to ± 3.6 volts, or less than 1 per cent.* An investigation of the sources of error has led us to believe that nearly all the variation from hour to hour

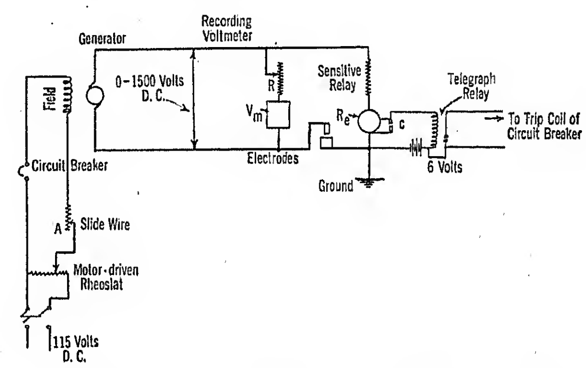

FIG. 1—SIMPLIFIED DIAGRAM OF CONNECTIONS

and from day to day is caused by variations in the paper. The accuracy of the results depends, of course, on the number of readings averaged for each point, and upon the variability of the material. With a more uniform material than paper, still more accurate results could be obtained with the same number of readings.

APPARATUS

Diagram of Connections. A simplified diagram of connections is shown in Fig. 1. All tests are made with direct current furnished by a 4000-volt generator. The field of this machine is separately excited from the 115-volt mains, a motor-driven rheostat being used to vary the voltage automatically. This rheostat is driven by a small synchronous motor, and twice a minute raises the generator voltage at a uniform rate from zero to a value somewhat above the breakdown point of the insulation.

†The authors wish to express their appreciation of the work of Mr. L. M. Dawes of the Elec. Engg. Dept., under whose direction most of the apparatus was constructed. Thanks are also due to the General Electric Co. for its help in the early stages of the work.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

This voltage is applied to the material between the electrodes. When puncture occurs, the rush of current operates the relay, *R e*, which trips the breaker in the field circuit of the generator. Across the line is also connected the recording voltmeter, *V m*. Every time the voltage rises, this voltmeter draws a line across its chart. The pointer continues to move slowly across the chart until breakdown occurs, when it falls back to zero due to the opening of the circuit breaker. The length of line is thus a measure of the breakdown voltage.

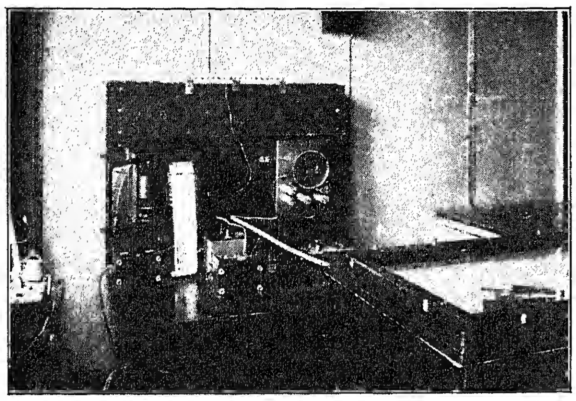

FIG. 2—INSTRUMENT BOARD

Just before the motor-driven rheostat is ready to start raising the voltage again, contacts on its rotor close and operate the feed mechanism. This pulls a fresh piece of insulation under the electrodes. At the same time, the circuit breaker closing coil is energized. The voltage is then built up as before. The cycle of operations is thus as follows: Voltage is raised slowly, puncture occurs tripping circuit breaker, feed mechanism operates, circuit breaker closes, voltage starts rising again. The cycle is repeated indefinitely.

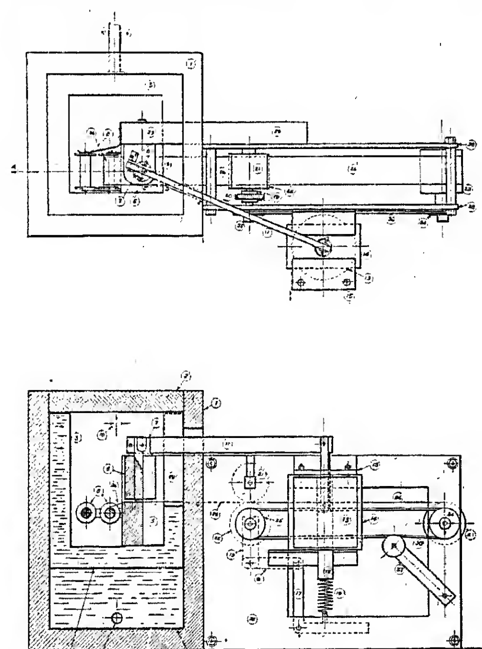

FIG. 3—ELECTRODE MECHANISM

Fig. 2 shows some of the apparatus. On the left of the board is the recording voltmeter. At the right is the sensitive relay. A series protective resistance of about 50,000 ohms is seen directly below the relay. The large box in the right foreground is called the constant humidity box.

Electrode and Feed Mechanisms. In the constant humidity box are the electrodes and the feed mechanism. As shown in Fig. 3, the lower electrode 5 is a copper block 2 in. sq. The upper electrode 7 is a copper rod 7/8 in. in diameter which slides up and down in the brass housing 6. The material to be tested, in the form of a long strip about 1 1/4 in. wide on the spools 8, passes between the electrodes and is wound up on the drum 23 after it has been punctured.

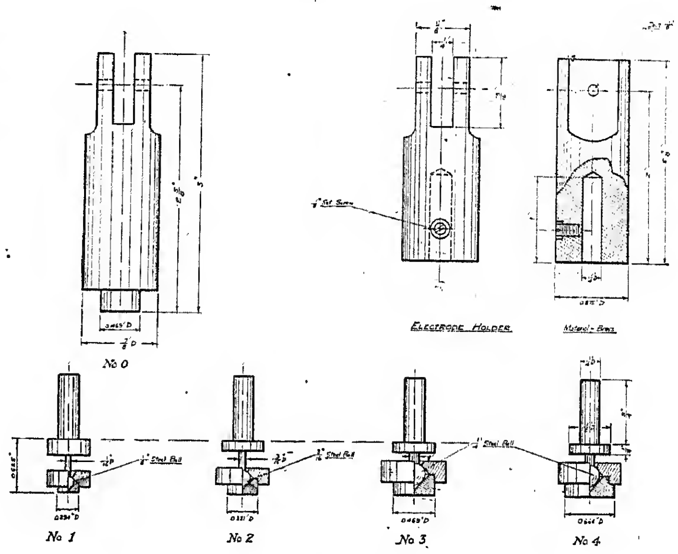

FIG. 4—ELECTRODES

After puncture occurs, the solenoid 13 is energized, lifting the plunger 12, and thus raising arm 11. This raises the electrode 7 slightly from the insulation and allows the strip to move. The movement of 12 also operates the lever 17 which moves the rolls 21 and 22 and brings a fresh portion of insulation between the electrodes. The plunger 12 then falls and the electrodes are again pressed against the insulating material with considerable pressure due to the weight of 11 and 12.

The electrodes are surrounded by the copper jacket 3. This is kept filled with oil which is circulated by means of a small motor-driven pump connected by the pipes 9 and 10. An electric heater in the piping system allows the temperature of the oil to be accurately controlled. For low temperatures a cooling coil immersed in an ice bath is used. A copper-advance thermocouple soldered to the lower electrode makes possible the accurate determination of the temperature. Wires from this thermocouple are run through the walls of

the constant humidity box and are connected to a potentiometer.

Electrodes. The same lower electrode was used in all the tests. The various upper electrodes are shown in Fig. 4. No. *0* was the one used in the earlier tests. It consists of a solid rod of copper, the end being turned as shown. The electrode face was ground to an

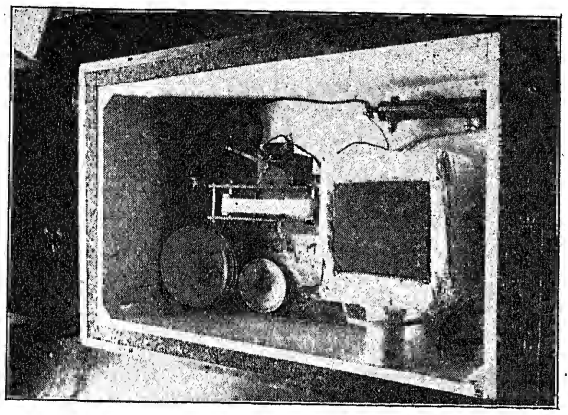

Fig. 5—View Looking Down into Constant Humidity Box

accurate fit with the lower electrode, using fine carborundum and oil. In this way, the electrodes made contact with the insulation throughout the area of the face.

To make absolutely sure that this was the case, the other electrodes were made. These electrodes were fitted with ball-and-socket joints so that they would press evenly on the insulation throughout the face.

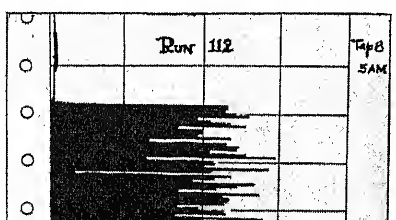

Fig. 6—Sample Voltmeter Chart

Range of scale = 325-700 volts using voltmeter tap No. 8

Electrodes 1, 2, 3, and 4 are used with the same holder. This is shown in the upper part of the figure. The faces were ground flat by using a piece of plate glass and some fine grinding compound. In all cases, the edges were rounded to a radius of about 0.001 in.

Control of Humidity. Fig. 5 is a view looking down into the constant humidity box, the cover being removed. The oil jacket surrounding the electrodes is shown in the lower part of the figure. The small fan in the upper part circulates the air over plates of phosphorus pentoxide in order to keep the humidity in the box at a very low figure. The sensitive hair hygrometer in the box indicates the per cent humidity.

Procedure

All the tests were made on General Electric condenser tissue 0.0005 in. thick. This was a good grade of rag stock, and was not varnished, oiled, or otherwise treated. This material was used, not because of any special interest in its properties, but because it seemed to offer a cheap and fairly good material which could be obtained in long strips. All tests were made with paper from a single roll.

Twenty-four hours before starting a run, the paper for that run was wound from the roll to a small spool. This was done in a special winding machine in order to avoid all wrinkles. This eighty feet of paper on the spool was then baked for eight hours in a vacuum at 72 deg. cent. to remove moisture. The spool was then transferred to the constant humidity box, the cover bolted down, and the fan run all night to insure a constant low humidity during the run which was started the next morning. In this way, one run could be made every day, the paper being baked the previous day and transferred to the box each evening.

From 800 to 1000 punctures were made in a day. The resulting voltmeter chart consisted of a large number of lines ruled by the voltmeter, the length of each line representing the voltage at which one puncture occurred. A portion of such a chart is shown in Fig. 6. The lines are ruled 40 to the inch. The daily average is obtained by adding all these puncture voltages on a calculating machine and dividing by the number of readings. Hourly averages are also sometimes used, each consisting of the average of the 100 to 120 readings taken in one hour.

Results

Preliminary Tests; Effect of Moisture. Preparatory to the regular tests, some runs were made to determine a good way of conditioning the paper. With such a hygroscopic material, considerable trouble was anticipated in eliminating all traces of moisture. There seemed to be no practical way of obtaining the actual moisture content of the paper under operating conditions. Our aim was therefore to develop a procedure which would produce consistent results, and to adhere strictly to this procedure in all runs.

Three runs made with the constant humidity box open to the air were as follows:

Run	No. readings	Temp. deg. cent.	Per cent humidity	Voltage (corrected to 20 deg. cent.)
15	239	19	5.8	588.6
16	222	21	8.7	571.0
17	1059	21	22.2	561.3

All values of voltage are referred to 20 deg. cent. by using a correction of -1 volt per deg. cent. A

considerable drop in voltage will be noted, due to increased humidity. As has been previously noted, the probable error of the daily average is about 3.6 volts. Three significant figures are therefore permissible. The fractional parts of a volt are probably meaningless and are retained merely to conform with the other runs of this group, some of which varied from each other by less than one volt.

The next investigation was to find how long the paper would have to be kept in the constant humidity box to reach a uniform condition of dryness. Several spools of paper were put in the box, phosphorus pentoxide was used, and the cover was bolted down. Under these conditions:

Run	No. readings	Temp. deg. cent.	Per cent humidity	Hours drying	Voltage (corrected to 20 deg. cent.)
18	1007	25	0.2	24	589.1
19	897	22	0.2	48	590.0
20	869	23	0.2	120	592.6

The results of these runs differ from one another by less than the probable error, and can thus be considered identical. Comparison of the hourly averages, however, shows a decrease in puncture voltage of 30 or 40 volts from the first readings of a run to the last. This indicates that the inner layers of paper on the spool were incompletely dried.

The next step was to bake the paper in an electric oven at 103 deg. cent. The results were:

Run	No. readings	Temp. deg. cent	Per cent humid.	Hrs. baked at 103 deg. cent.	Voltage (cor. to 20 deg. cent.)	Volts dev. from aver.
22	1064	23.6	0.2	8	614.6	−0.8
23	1040	26.1	0.2	17	616.4	+1.0
24	971	25.7	1.2	8	615.2	−0.2
					Av. = 615.4	

The hourly averages in these runs showed no downward trend with time, indicating uniform baking throughout the spool. The standard deviation of the individual readings was 46.0 volts, which is in agreement with later tests. The probable error of the daily average predicted from the σ of the individual readings is 1.0 volt. The agreement among the daily averages is thus even better than would be predicted from the σ of the individual readings, neglecting all long-time variations in the paper. Therefore, the small daily variations in the above runs are evidently due to some fortuitous combination of circumstances which cannot be expected to obtain generally. In fact, all the later runs show a greater probable error of the daily average than predicted from the single readings, due undoubtedly to long-time variations in the quality of the paper.*

*See "Precision of Results."

This method of baking the paper was used in all tests up to Run 50. A change was then made to vacuum baking, which was used in all subsequent runs. It will be noted from Fig. 15 that the tests made with the two methods gave the same results. That there was very little moisture in the paper is also indicated by the fact that there is no break in the $E - \theta$ curve* near 100 deg. Our conclusions, then, are that the effect of moisture on the breakdown voltage is not as great as might be expected, and that there seems to be no difficulty in getting the paper dry enough to insure uniformity from this aspect.

Effect of Temperature. It seems reasonable to expect the thermal theories to apply in a great number of cases of breakdown. It seems equally likely, however, that the theories will fail in other cases such as sudden application of voltage, very low ambient temperatures, or extremely thin materials. In such cases there is little possibility of progressive heating of some path through the insulation, and breakdown must be of a different nature. There appear to be, then, at least two mechanisms of breakdown† which we will call "thermal" breakdown and "disruptive" breakdown. The question then arises as to the limits of applicability of each theory. This is a subject for experimental investigation.

If puncture voltage be plotted against temperature,

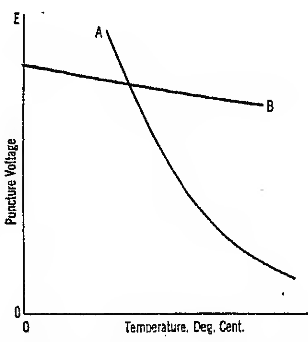

Fig. 7—Probable Shapes of $E - \theta$ Curves

A—Predicted by thermal theories of breakdown
B—Probable shape for distruptive breakdown

the thermal theories predict an exponential curve A, Fig. 7. Purely disruptive punctures, on the other hand, would probably be nearly independent of the temperature, as in the curve B. It seems likely, therefore, that if a curve were obtained for any material over a wide enough range of temperatures, thermal breakdowns

*Fig. 8.

†Hayden and Steinmetz, Bibliography No. 8, discuss several possible mechanisms of breakdown. In this connection, Rogowski says: "The opinion that breakdown is caused solely by heating must be abandoned in the case of thin plates, low temperatures, and sudden applications of voltage. On the other hand it may be correct for thick plates, high initial temperatures, and sufficiently long voltage applications; though a decisive verdict is not possible at present due to lack of suitable experimental material."

would occur in part of the range and disruptive breakdowns in the remainder. A combination of A and B would result. Such a curve would prove the existence of both kinds of punctures, and might lead to some criterion by which the transition point could be predetermined.

The results obtained are shown in Fig. 8. The temperature was varied from − 2 deg. to + 130 deg. cent., as wide a range as could be conveniently obtained. Each point represents a daily average of from 800 to 1000

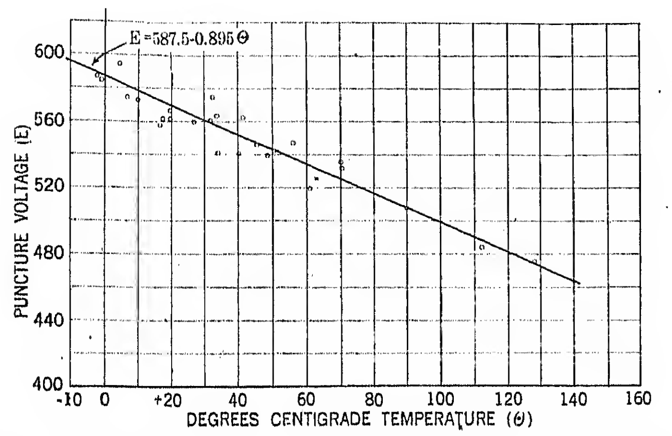

FIG. 8—BREAKDOWN VOLTAGE AS A FUNCTION OF TEMPERATURE

Runs 103-130

G. E. condenser paper baked in vacuum for 8 hr. at 72 deg. cent. before each test
Each point represents the average of from 500-1000 readings

readings. It will be noted that a rise in temperature of 100 deg. cent. causes a diminution in puncture voltage of only 15 per cent.

The curve appears to be of the form B rather than A.* Further analysis given in Appendix A leads to the same conclusion; namely *none of the punctures obtained in these tests occurred according to the thermal theories of breakdown.* This is probably due to the very thin material used and the excellent heat-transmitting properties of the electrodes.‡ Further tests are now in progress with thicker materials with which it is hoped to obtain curves of both the A and B types.

Effect of Electrode Area. Considerable work has been done in the past regarding the effect of electrode size. In 1913, Mr. F. M. Farmer[20] presented the results of tests on varnished cambric and hard rubber with electrodes of various sizes. Mr. Milnor[44] showed that, if we consider the insulation to be non-homogeneous, each elementary area between the electrodes having its individual value of dielectric strength, and if we assume further that these values are distributed according to the normal form of probability curve and that puncture occurs at the weakest point, then the breakdown voltage should be

$$E = C_1 - C_2 \log A$$

A is the area of the electrodes and C_1 and C_2 are constants. This is known as the "weak-spot" theory. Farmer's curves were of this form. The experiments of Gewecke and Krukowski[21] also seem to support the weak-spot theory. Further work by G. Y. Fong[23] and

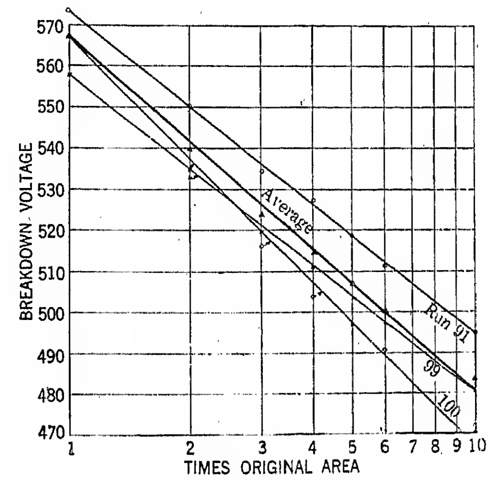

FIG. 9—BREAKDOWN VOLTAGE AS A FUNCTION OF ELECTRODE AREA

Electrode No. 1

Kennelly and Wiseman,[24] however, have cast some doubt on the validity of the theory, and nothing really conclusive seems to have been decided.

In connection with an investigation of the various factors which might have caused errors in the $E - \theta$ curve, some runs were made to determine the effect of electrode area. While the evidence is not conclusive, it seems to support the weak-spot theory.

If the weak-spot theory is correct, the breakdown voltage obtained with large electrodes of area nA should be the same as the lowest value obtained in n consecutive tests made with electrodes of area A. In other words, puncture should occur at a certain voltage corresponding to the weakest spot in a given area, regardless of whether this area is tested all at one time by the use of large electrodes, or is tested one section at a time with small electrodes. Thus if a large number of tests is available, using one size of electrodes, the puncture voltage for electrodes of twice this area should be obtainable in the following way: Consider the results in groups of two, discard the higher value in each case, and take a new average of the remaining figures. Similarly, the breakdown voltage for three times the original area should be obtainable by dividing the readings into groups of three and averaging the lowest values of each group.

*In accordance with the Joffe theory of breakdown which has recently appeared, our curve is a measure of the number of free ions existing in the material at various temperatures.

‡See also Appendix B. Since our paper was written, some very valuable work by Inge, Semenoff, and Walther has been published[52]. $E - \theta$ curves are obtained showing a decided break where the mechanism of breakdown changed from the disruptive to the thermal type.

This was done in the case of Electrode No. 1 as shown in Fig. 9. The area of this electrode was taken as unity for convenience. It will be noted that the result is very accurately of the form

$$E = C_1 - C_2 \log A$$

as was predicted by Milnor. Our tests, therefore, support his proof. His assumption of a normal distribution of puncture voltages (an assumption which at that time had not experimental verification) is also verified by our tests.*

Similar analyses were made with electrodes of twice and four times the area. The results† are shown in Fig. 10. To be a perfect check of the weak-spot theory, the three curves should coincide. Though all curves have practically the same slope, No. 2 is about 2 per cent higher and No. 1 about 2 per cent lower than No. 3. Probability theory shows that this is too large a discrepancy to be due entirely to random variations in the paper. It is most likely caused by a "seasoning" action of the electrode faces, an effect which unfortunately was not discovered until after these runs were finished.‡ It is also possible that some thermal or other effects are present which are ignored by the weak-spot theory. The tests, however, indicate that the theory is at least approximately correct.

The Standard Deviation. Fig. 11 shows the frequency

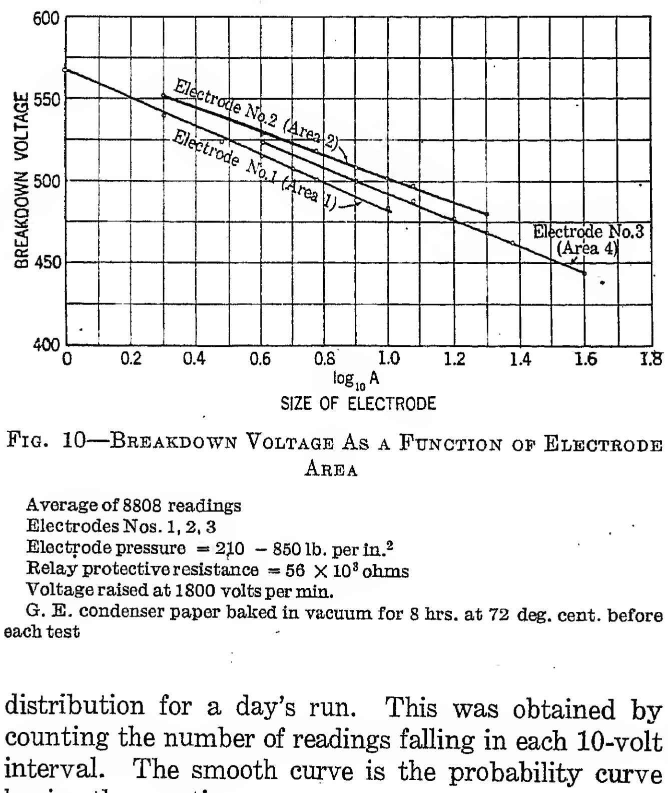

FIG. 10—BREAKDOWN VOLTAGE AS A FUNCTION OF ELECTRODE AREA

G. E. condenser paper baked in vacuum for 8 hrs. at 72 deg. cent. before each test

distribution for a day's run. This was obtained by counting the number of readings falling in each 10-volt interval. The smooth curve is the probability curve having the equation—,

$$y = \frac{1}{\sigma \sqrt{2\pi}} \epsilon^{-\frac{x^2}{2\sigma^2}}$$

It will be noted that the points of our frequency distribution fall fairly well on this curve, showing that the distribution is of the normal form such as is obtained for the variations of any quantity governed purely by chance.§ Distributions obtained on other runs are very similar to the one shown. The highest point of the curve is, of course, at the arithmetic average of all

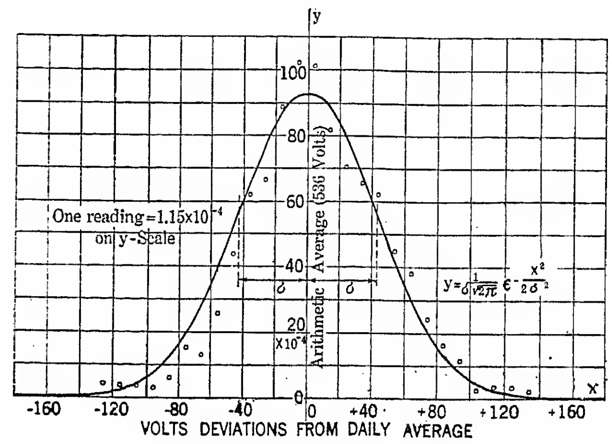

FIG. 11—TYPICAL PROBABILITY CURVE

Run 108
σ = 43.1 volts
$\frac{1}{\sigma\sqrt{2\pi}}$ = 92.6 × 10^4

the readings, and thus is the most probable voltage of breakdown.

The constant σ in the above equation is called the *standard deviation* or *dispersion*. It is a very important constant in statistical work, since it completely specifies the distribution, and thus takes the place of a mass of data. The standard deviation was obtained from the puncture voltage readings by the use of the equation

$$\sigma = \sqrt{\frac{\Sigma\ (\delta)^2}{n}}$$

where $\Sigma\ (\delta)^2$ is the sum of the squares of the deviations from the mean and n is the number of readings. In this case, σ = 43.1 volts. A more uniform and homogeneous material would have a more peaked curve and therefore a smaller value of sigma. A more variable material would have a larger sigma. Thus the constant σ is a measure of the inherent variability of the material.*

It is believed that the standard deviation will be of practical importance in future insulation engineering. Sigma is a constant of the material, just as important in its way as puncture voltage. The puncture voltage indicates the average value at which breakdown occurs; the standard deviation tells how much variation there

*See Fig. 11.

†All tests were made at a temperature of 48 deg. cent., humidity of 0.4 to 4 per cent, and a voltage rise of 1800 volts per min.

‡See "Effect of Polishing Electrodes."

§See, for instance, Bibliography, 44-50.

*It also includes of course, the accidental errors of measurement.

will be from sample to sample. By knowing both these constants, the insulation designer can put his work on a much firmer foundation than would otherwise be possible. The constant should also be of use in the specification of insulating materials. The variability of the material bought by large cable or condenser manufacturers, for instance, is of the utmost importance to them. By specifying σ and keeping it up to standard by tests made on samples from each batch received, the manufacturer would eliminate one of the variables which tend to produce a non-uniform product.

Precision of Results. As previously noted, Fig. 12 shows the results of 16,000 punctures made under the same conditions. The tempe ature was kept at 40 deg. cent., the humidity was between 0.2 and 0.4 per cent, and the electrode No. 0 was used throughout. Each point represents an hourly average of between 100 and 120 readings. The ordinates are the deviations of the hourly averages from the average of the day in which they occurred. The abscissas are merely consecutive hours of run. With the exception of the first run, the data do not appear to have any decided trend, either up or down, but seem to be purely random variations such as would be expected from variations in the paper itself.

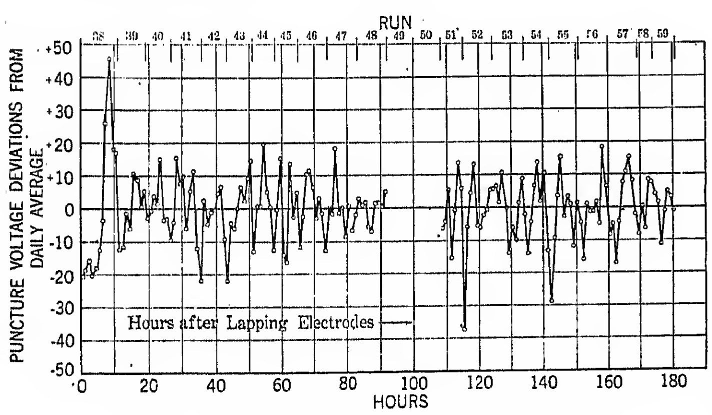

Fig. 12—Voltage Deviations, Runs 38-60

(Hourly averages minus daily average)

That the variations are random and follow the normal law is shown by Fig. 13. The points give the frequency distribution of these hourly averages. The smooth curve is the theoretical probability curve. The points fit the curve about as well as could be expected with such a small number of data, only 150 points. The next curve, Fig. 14, shows the deviations of the daily averages from the average of the eighteen runs from No. 39 to 59, inclusive.*

A statistical analysis was made of all the data, Appendix C. The actual values of σ are as follows: For the individual reading, 40 volts; for the hourly average, 9.19 volts; for the daily average, 5.3 volts. Comparison of the hourly and daily sigmas with the corresponding values predicted from the σ of the individual readings by probability theory, shows that in both cases the actual values are too high. The discrepancy of the daily value is, however, not much greater than that for the hourly sigma. This would seem to indicate that the unavoidable changes in humidity and baking (variations which did not occur from hour to hour) were not responsible for the variations in the daily average. It is thought that both hourly and daily

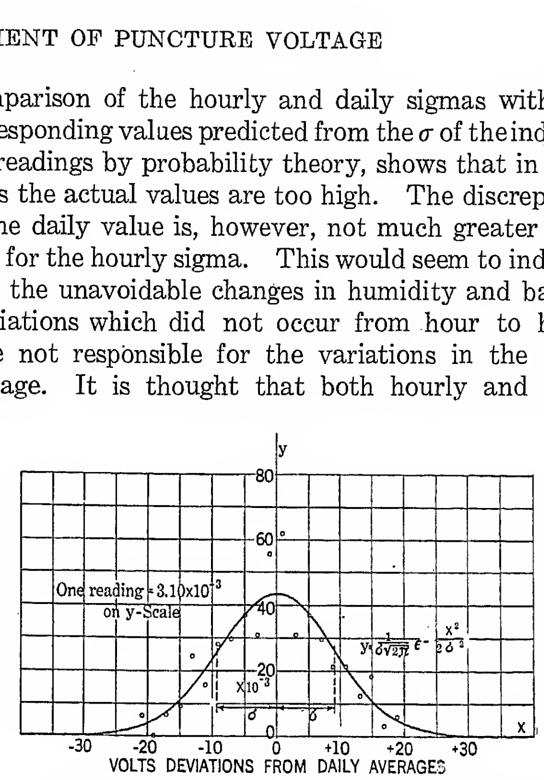

Fig. 13—Probability Curve of Hourly Averages, Runs 39-60

σ = 9.19 volts

$$\frac{1}{\sigma\sqrt{2\pi}} = 0.0434$$

variations are due principally to inherent variations in the paper itself.

Appendix C also shows that the probable error of the

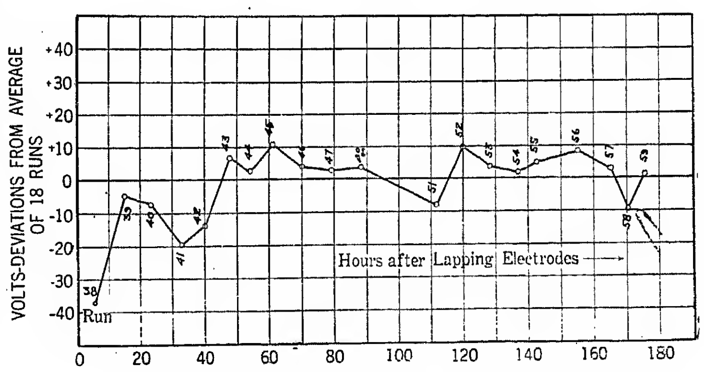

Fig. 14—Deviations of Daily Averages from Total Average of 18 Runs

All readings corrected to 30 deg. cent.

daily average is 3.6 volts, and thus the daily average is correct to less than one per cent.† Analysis of the runs used in obtaining the $E - \theta$ curve, Fig. 8, shows a similar situation. The probable error of the daily average in this case is 4.7 volts, giving again an error of less than 1 per cent. Thus the accuracy obtained by the machine is evidently much greater than could have

*Run 38 was not used because of its low average. This is explained in the next section. Runs 49 and 50 were made, but the hourly averages were not computed.

†This, of course, ignores any constant errors which may have been present in all the tests.

been reached by the usual methods without an undue expenditure of time and labor.

A list was made of all possible sources of error. These included variations in the temperature and time of baking, variations in humidity, electrode size and pressure, rate of voltage rise, value of protective resistance, time which elapsed after polishing the electrodes, voltmeter calibration, and errors in temperature measurement. Nearly all of these factors were investigated over a wider range than would be likely to occur accidentally.

The effect of polishing the electrodes was found to be

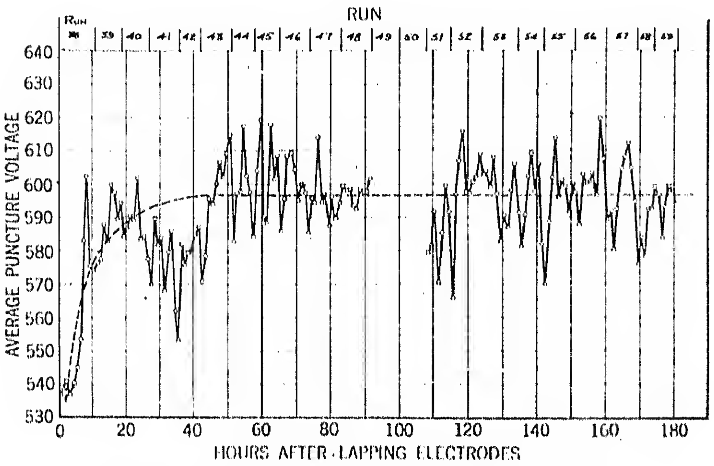

Fig. 15 Hourly Averages, Runs 38-60

All readings corrected to 30 deg. cent.

Dotted curve indicates the upward trend of voltage due to seasoning of the electrodes

very considerable, as will be shown later. Too high a protective resistance was also found to have great effect, since it produced sluggish operation of the relay. Care was taken to eliminate both of these errors.‡ The other factors were shown to have very little effect in the limited range through which they might conceivably have varied. It seems unlikely that any of them caused variations of more than 1 or 2 volts. This again goes to show that most of the variation was due to the paper itself.

Effect of Polishing Electrodes. It has already been noted that the puncture voltage in Run 38 was very low. This is also shown in Fig. 15 where hourly averages are plotted against hours' use of the electrodes after polishing.§ Here the low puncture voltages obtained after polishing are very evident. To make sure that this was not a freak happening, hourly averages were plotted for a number of other runs, and in each case the time of polishing the electrodes was clearly shown by a set of readings lower than those obtained at any other time.

Brass and copper electrodes are commonly used for breakdown tests. It is probable that this phenomenon has been present in most tests, though it appears not to have been noticed before. Evidently if tests are made on the very steep part of the curve, the results will be much more inconsistent than would otherwise be the case. In our tests, it was necessary to discard at least 1000 readings after the electrodes were polished.

The cause of this trouble is not known. Current at breakdown was limited by the protective resistance to such a low value that there was no pitting of the electrodes nor was there any apparent roughening of the surface. One possible explanation is that the puncture produces an insulating coating on the electrode surfaces. Examination of the electrodes shows that each puncture causes a small black mark on the electrodes. These spots distribute themselves fairly evenly over the entire electrode surface. After a day's use, the faces reach a state of more or less uniform blackening, which is not altered much by subsequent runs. If each spot introduces a high resistance in series with the paper below it, puncture will tend to occur at places where there are no spots. This will have the effect of decreasing the effective surface, and will increase the puncture voltage accordingly. After a large number of punctures, the blackening effect will reach a nearly constant value, with like effect on the puncture voltage. Tests are now being made to determine if this effect can be eliminated by the use of a nonoxidizing metal for the electrodes.

Conclusions

A curve of puncture voltage against temperature was obtained for 0.0005-in. condenser paper in the range from 2 deg. to + 130 deg. cent. The puncture voltage was found to decrease uniformly at about 0.9 volt per deg. cent. rise. Comparison of these data with the thermal theories of breakdown indicates that none of these punctures occurred according to the thermal theories, but were evidently of the disruptive type.

It was found that the puncture voltage measurements were distributed according to the normal law. A set of 8800 readings with different sized electrodes appears to support the weak-spot theory, though the evidence is hardly conclusive.

The standard deviation of the readings was found to be a constant of the material, independent of the electrode area and only slightly affected by temperature and number of readings. It is believed that this constant will be of considerable use in the specification of insulation, since it is a measure of the variability of the material.

It was found that the inherent variability of the paper was not confined to causing variations from reading to reading, but also caused long-time variations from hour to hour and from day to day. This reduces the accuracy of the daily averages below the values predicted by the theory of probability.

An analysis of the results indicates that the variations from hour to hour and from day to day are largely due to variations in the paper itself. An investigation

‡Except in the investigation of electrode area, where the effect of polishing the electrodes was probably of importance.

§The gap at Runs 49 and 50 is due to the fact that hourly averages were not computed for these runs.

was made of the various possible sources of error, and it appears that no one of them could have caused an error of more than one or two volts. The probable error of the results is shown to be less than 1 per cent. This precision is evidently considerably higher than could have been obtained in the ordinary way without a great expenditure of time and labor.

Copper and brass electrodes are commonly used for puncture tests. Our experiments, however, indicate that with such electrodes there is a "seasoning" effect. This produces a marked change in puncture voltage unless the electrodes are cleaned after each puncture or are allowed to reach a steady state before readings are taken. Such a condition was obtained only after about 1000 readings.

Appendix A

THERMAL THEORY OF THE $E - \theta$ CURVE

According to the thermal theories of breakdown, puncture occurs when

$$\frac{E^2}{\rho} = C, \text{ a constant*}$$

where E = voltage gradient at breakdown,

ρ = resistivity of the weakest path at the temperature of the surroundings, θ.

Physically, this means that for a condition of instability to obtain, it is necessary that the rate of heat generation per unit volume (E^2/ρ) shall reach a certain critical value (C). This value is a constant for a given material. It depends upon the thermal conductivity, the temperature coefficient, and also, in Rogowski's theory, upon the thickness.

If we assume that the resistivity is an exponential function of the temperature

$$\rho = \rho_0 \, \epsilon^{-\gamma\theta}$$

then it is evident that

$$E = \sqrt{C \rho_0} \, \epsilon^{-\frac{\gamma}{2}\theta}$$

Thus the γ obtained from resistivity measurements will determine the change of puncture voltage with temperature.

Unfortunately, no resistivity measurements have yet been obtained on the paper used in these experiments. According to the work of J. E. Shrader[30], however, untreated fish paper has a temperature coefficient of about 0.07. Assuming this value for γ, we find that the puncture voltage at 100 deg. cent. should be

$$E_{100} = 587.5 \, \epsilon^{-\frac{0.07}{2}(100)} = 18 \text{ volts}$$

instead of the 498 volts actually obtained.

If, instead of a straight line, we use an exponential to approximate the data of Fig. 8, we find

$$E = 587.5 \, \epsilon^{-0.0016\theta}$$

The value of γ is thus 0.0032. That such a value is very improbable is shown by the following table:

Authority	Material	γ
J. E. Shrader[30] ...	Untreated fish paper, vacuum dried	0.07
J. E. Shrader[30] ...	Untreated fullerboard, vacuum dried	0.07
J. E. Shrader[30] ...	Paraffined fish paper	0.104
H. H. Poole[29]	Mica	0.051
H. H. Poole[29]	Glass	0.109
E. Mündel[17]	Glass	0.084
Landolt-Bornstein[5]	Glass	0.120
Landolt-Bornstein[5]	Hard rubber	0.023
Landolt-Bornstein[5]	Porcelain	0.084

Appendix B

Some work of E. Mündel[17] has recently come to our attention, and a set of his curves has been replotted in Fig. 16. The material used in the tests was glass 0.4 mm. thick. Two curves, A and B, have been added to Mündel's results. Curve A is an exponential with ($\gamma/2 = 0.0171$). The straight line B falls 15 per cent with 100 deg. cent. increase in temperature just as in Fig. 8.

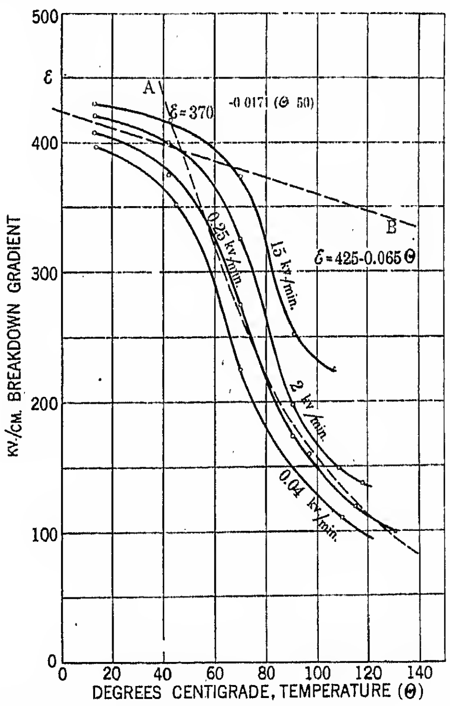

FIG. —16 PUNCTURE OF GLASS 0.4 MILLIMETERS IN THICKNESS

(From Mundel—*Archiv. f. El.* 15, 1925, p. 338)

These curves are a possible explanation of Mündel's results. The part of his curves from 50 deg. upward is evidently caused by thermal breakdowns, while the lower temperature punctures were probably disruptive.

*According to Wagner, loc. cit., formula 2,

$$\frac{E^2}{\rho} = \frac{k}{\gamma \, \epsilon}$$

k = thermal conductivity,

γ = temperature coefficient of resistivity,

ϵ = 2.71828 . . .

This is based on the assumption that heat flow is radial from a thread into the surrounding insulating material.

Rogowski assumed that heat flowed only into the electrodes, and obtained the result, Rogowski, loc. cit., Formula 11,

$$\frac{E^2}{\rho} = \frac{8\,k}{\gamma\, D^2}$$

where D is the thickness of the insulation. The only difference is in the constant C.

It will be noted that all the curves appear to approach the slope of B as the temperature is decreased, while at the higher temperatures they approximate exponentials about as closely as the usual curves for resistivity do.

The value ($\gamma = 0.034$) from curve A seems to be a little low for glass; see table in Appendix A; but the discrepancy may be due to the fact that the resistivity of most insulating materials is a function of voltage as well as temperature, a fact which is neglected in the thermal theories.

Mündel's results, therefore, indicate the existence of both mechanisms of breakdown and show that the transition point for this particular case is about 50 deg. cent.

Thermal breakdowns are probably obtained in Mündel's tests and not in ours because of the difference in thickness of the two materials, his glass being about 30 times the thickness of our paper. All of our tests are undoubtedly on the straight line far to the left of his curves.

It is evident that for practical purposes, nothing could please the insulation expert more than to be sure that his insulation would operate on curve B rather than A, since its breakdown strength would then decrease so little with temperature. With a more thorough knowledge of insulation, the future engineer may be able to avoid thermal breakdowns altogether.

Appendix C

The following analysis was made:

Total readings, Runs 39-59, inclusive, = 16,505
Total hours . . . . = 154
Total days . . . . = 19

Av. hrs. per day = 8.11
Av. rdgs. per day = 869
Av. rdgs. per hr. = 107

From individual readings:

σ of one reading = 40 volts

$$\sigma \text{ of hourly aver.} = \frac{40}{\sqrt{107}} = 3.86 \text{ volts}$$

$$\sigma \text{ of daily aver.} = \frac{40}{\sqrt{869}} = 1.35 \text{ volts}$$

$$\sigma \text{ of total} = \frac{40}{\sqrt{16505}} = 0.31 \text{ volts}$$

From hourly averages:

σ of hourly aver. . . . . = 9.19 volts

$$\sigma \text{ of daily aver.} \quad \frac{9.19}{\sqrt{8.11}} = 3.22 \text{ volts}$$

$$\sigma \text{ of total} \quad \frac{9.19}{\sqrt{154}} \quad . \quad . \quad = 0.74 \text{ volts}$$

From daily averages:

σ of daily aver. . . . . = 5.30 volts

$$\sigma \text{ of total} = \frac{5.30}{\sqrt{19}} \quad . \quad . \quad = 1.22 \text{ volts}$$

Probable error of daily aver. = $5.30 \times 0.6745 = 3.6$ volts
Probable error of total = $1.22 \times 0.6745 = 0.82$.

These results can be tabulated as follows:

STANDARD DEVIATION

	Individ. rdg.	Hourly	Daily	Total	Daily σ / σ by Ind. rdgs.
By indiv. rdgs.	40v	3.86	1.35	0.31	1.0
By hourly aver.		9.19	3.22	0.74	2.4
By daily aver.			5.30	1.22	3.9

Discussion

W. W. Shaver: Mr. Moon stated that his results indicated that the breakdown was not a pyroelectric effect. I should like to mention some experiments which we have been carrying out on Pyrex and porcelain insulators which seem to warrant a similar conclusion.

These consisted in developing partial punctures; that is, carrying a puncture test almost to the point of breakdown, and then breaking the circuit and examining the partial puncture in the material. We have some photographs showing what might be described as "petrified lightning" in the breakdown in the Pyrex insulators. The discharge very much resembled a lightning flash permanently impressed in the glass. In the porcelain insulators, of course, we could not observe this in the same way, but by staining the material, we have found means to show that breakdown occurs in a similar manner. When examined under the microscope, the appearance of these partial punctures indicated that the breakdown was not due to a pyroelectric effect, but more probably to some type of ionization in the material.

F. M. Clark: In Pittsfield, we have worked for several years trying to devise a theory for insulation failure. We may not have made any more progress than other electrical laboratories, but we have reached some definite conclusions with regard to dielectric behavior. One conclusion is that the electrical breakdown of air-impregnated insulation is certainly not a breakdown phenomenon which we can explain on the basis of the pyroelectric theory. That checks, I believe, with the conclusions drawn by the authors. Air-impregnated insulation appears to give a breakdown which is a function of the chemical behavior and dielectric strength of air.

On the fifth page of their paper, the authors discuss the effect of large and small electrodes. They apparently reach the conclusion that the difference accompanying the use of large and small electrodes is a weak-spot difference. From such familiarity as I have with the paper they are using, I do not see how they can reach any other conclusion.

If the authors desire to get further evidence of the presence of weak spots, my suggestion would be to take a head set and locate those areas with low-voltage direct current.

In our work, we have extended the investigation to cover a number of laminations of this same type of paper as well as thick material, such as pressboard. We still find that the small electrodes give higher values than the large ones. This and other related observations make it almost conclusive to us that there is some effect present other than that which we can attribute to weak spots mechanically formed during the manufacture of the paper.

I was interested in the results with polished brass electrodes. We found the same thing. However, we have been led to believe that in all probability the low breakdown which is obtained for such thin materials when tested with new electrodes is due to the fact that the machinist has not polished the electrode surface sufficiently. With low-voltage direct current, weak-spot tests invariably show a larger number per sq. ft. with a new set of electrodes than with an old set. With frequent use, this difference between the electrodes tends to disappear. We have about concluded that the difference is largely due to a surface condition of the electrode which is mechanical and not chemical in any way.

Herman Halperin: In the body of the paper, the authors carefully point out the fact that the paper is only one-half a mil thick and for this reason thermal factors are favorable to disruptive breakdown.

Thermal breakdown. The equation for thermal breakdown is

$$E^2/\rho = C \text{ (Appendix A)}$$

Now, this equation does not contain a term for t (= time) since it is tacitly assumed that voltage is raised at a slow rate.

and the equation is the boundary or limiting value of the stable or steady-state condition. It takes a few hours to reach a steady condition. However, in Bush's tests, 100 to 120 readings were taken per hour. This is at the rate of two per minute, and assuming that half of the time is consumed in relay operation, feeding the tape, etc., the voltage must have risen at least 600 volts in 15 sec., or 40 volts per sec. This is far from a steady-state condition and it may well be that a more critical study of the thermal theory including the time and thermal storage coefficient of the paper would yield results consistent with the data.

At the end of Appendix B, they have this sentence: "With a more thorough knowledge of insulation, the future engineer may be able to avoid thermal breakdowns altogether."

That is, to my mind, a very nice hope, but I don't believe the authors have presented enough data to warrant that possibility.

Now, in Chicago, during the past few years, we have made over 300 tests at various times and durations on impregnated paper insulation in underground cables. We have found that about 75 per cent of the failures occurred in the region of the cable where the sheath temperature was higher than the adjacent sheath temperature. During the time the voltage was on the cable, our testing men went along the cable and felt it with their hands, and whenever they discovered a point a little hotter than the normal cable temperature, they placed the thermometer on the sheath and in that way we got the data as to the location of the so-called hot spots.

Furthermore we have found that a larger percentage of the failures was at hot spots when we had the thicker insulations, and so with real thin insulation, there may be more dissipation of the heat longitudinally so that it does not perhaps manifest itself in these hot spots.

Variation of thickness. If the failure is "disruptive" and follows "weak-spot" theory then running 1, 2, 3, . . or n paper layers through together, the dielectric strength should increase faster than the thickness of the layers. I should expect the equations to be of the form

$$E = E_1 (n + C \log n)$$

where E is strength of n layers and E_1 is the strength of one layer (as already determined). In other words, the weak spots would not line up and two papers would be far stronger than two times one paper.

However, on the other hand, if the thermal law were large or predominant, the strength could not be greater than

$$E = N E_1$$

and probably would follow the law

$$E = \sqrt{N}\, E_1\, n^{(1-x)}$$

If the failure were a complex combination of thermal and disruptive effects, (as is very probable), then the dielectric strength of several layers could follow the law

$$E = \phi (n) E_1$$

where $\phi (n)$ could be greater or less than unity for n = small number (1, 2, or 3, etc.). This may explain why different investigators may have found

$$E = n E_1$$

$$E = (n)^{3/4} E_1$$

$$E = \sqrt{n}\, E_1, \text{ etc,}$$

Now, Bush and Moon are in an excellent position to throw some light on this dispute by making identical tests with $n = 2$, $n = 3$, etc., up to the limit of the generator, 4000 volts (using wider strips, if necessary). Perhaps they could go as high as $n = 5$. Of course, they would have to be very careful about the pressure, since I am assuming thickness $t = n\, t_1$.

Variation of material. The tests described are on dry paper, unimpregnated. Without great complication, I believe it entirely feasible to surround the electrodes with an oil bath and have the paper run through this bath—(several zig-zag passes around several rolls under oil). The oil should be continuously renewed with degasified oil—the oil to flow in a closed cycle from the bath, into a vacuum chamber, pumped out and through a filter back into the bath. A surface float would prevent much gas from being absorbed at the surface during the short time the oil remains in the bath. Then the paper (being so thin), would quickly saturate with oil by capillary action, and small air bubbles trapped in the fibers would be quickly absorbed by the degasified oil. The test would then be a true test of oil-impregnated paper.

Again, several thicknesses n should be tried up to the limits of the apparatus. They should be spaced apart during impregnation and combined under the electrode only at the last minute.

Also it might be feasible and very valuable to adapt the apparatus to test oil films. All that is necessary is to have a continual flow of oil in the bath and a strip (or strips) of paper with perforated windows moved one at a time under the electrode. These "windows" would serve the double purpose of making the oil stagnant during test and positively sweeping it out clean for the next test.

Correlation. Then, having the breakdown strength of paper, oil, and impregnated paper separately, all with variations of thickness and temperature, the probability is high that much more will be known regarding the dielectric strength of "solid" oil-impregnated paper insulation. For the effects of ionization a separate analysis would be necessary but much simplified by exact knowledge of the "solid" insulation in series and parallel with the ionizing voids.

Wm. A. DelMar: Messrs. Bush and Moon have made an important contribution to the study of dielectrics in calling our attention to the importance of a large number of tests of dielectric strength, in order to obtain significant averages. Workers on dielectrics are indebted to them for developing an apparatus for putting this principle into effect.

The actual results obtained in their tests, however, are of doubtful value, due to the nature of the dielectric which they have chosen. In the first place, unimpregnated paper is merely air baffled by a tangle of fibers, and is not at all representative of a solid dielectric. Secondly, the use of samples as thin as ½ mil., especially in a material of this character, was bound to result in the way they have shown. It was not necessary to make tests in order to discover the relation shown in Fig. 11 of the paper. I therefore feel that they have contributed little or nothing towards settling the disputed explanation of the lowering of dielectric strength with increase of area.

The idea illustrated by their Fig. 7 may prove to be an important one for researchers on dielectrics if the slopes of the Curves A and B are really as different as shown. That such is the case is indicated by their analysis of the work of Mündel.

R. H. Marvin: (communicated after adjournment) This paper is of great interest on account of the ingenious methods used and the accuracy and completeness of the data obtained. However, the dielectric used in these tests,—untreated paper,—raises some question as to their significance.

If a piece of paper is examined with a microscope, it is seen to consist of great numbers of interlaced fibers. Such a structure indicates air spaces between the fibers, which is in accordance with its well-known porosity. The question then arises whether a puncture test on such a material gives a true puncture of the paper substance, or merely a breaking down of the air in the interstices. This is best checked by a comparison with the breakdown value of an equal air-gap.

Some excellent data on the strength of small air-gaps are given in, "The Sparking Distance Between Plates for Small Distances," Robert F. Earhart. *Philosophical Magazine.* 6th Series. Vol. I. 1901. Pp. 147-159. From Fig. 4 of this article the following values for various gaps and pressures are obtained:

Gap		Direct-Current Breakdown Voltage		
		Pressure, centimeters of mercury		
Millimeters	Inches	40	76	152
0.01	0.00039	340	385	490
0.02	0.00079	400	460	700
0.03	0.00118	460	530	900

The temperature is given as room temperature, and will be taken as 20 deg. cent. Since we may assume that changes in density caused by either temperature or pressure have the same effect, these data permit determining the breakdown at different temperatures as well.

Fig. 8 of the paper under discussion gives the breakdown strength of untreated paper 0.0005 in. (0.0127 mm.) thick at temperatures of from 0 deg. to 140 deg. cent. The curve is a straight line giving a puncture voltage of 586 at deg. cent., and 464 at 140 deg. cent. From the data given by Earhart let us determine these values on the assumption that the paper acts merely as a spacer for an air-gap. If the relative air density is taken as 1 at 20 deg. cent., then it will be 1.073 at 0 deg. cent., and 0.710 at 140 deg. cent. Plotting the values in the table and taking the values for a 0.0005-in. gap gives the following:

Pressure, centimeters	Relative air density	Breakdown voltage
40	0.527	354
76	1.000	406
152	2.000	547

Plotting the breakdown voltage against relative air density, we obtain the breakdown voltage at 0 deg. cent. (relative air density 1.073) as 415 volts, and at 140 deg. cent. (relative air density 0.710) as 373 volts. Thus the value for air at 0 deg. cent is 70.8 per cent of the value for paper, and the value at 140 deg. cent is 80.4 per cent. Both values for air are therefore a little low, but by nearly the same percentage.

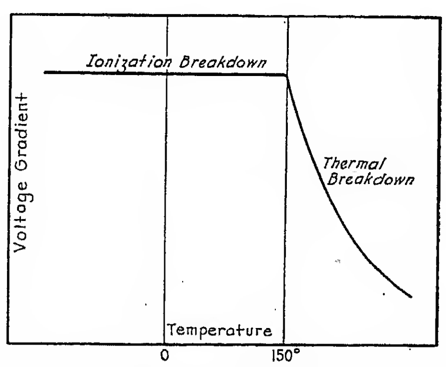

FIG. 1—BREAKDOWN GRADIENT OF GLASS

Thickness = 1 mm.

From Joffe, Kurchatoff, and Sinelnikoff, *Jour. of Math. and Physics*, April 1927

There is also the possibility that the path of the spark among the paper fibers is not straight, but winding. This would increase the breakdown voltage of the air path, and bring the calculated values for air more nearly in accordance with the observed values for paper.

While it must be admitted that the data presented are not sufficient to prove that the untreated paper acted simply as an air-gap, still the relation is sufficiently striking to appear to deserve further study.

P. H. Moon: I was much interested in the suggestions made by Mr. Halperin. There is, of course, an immense field for further work along these lines; and our work, so far, can hardly be considered as more than a preliminary.

I agree with Mr. Del Mar that the material used was not just paper but was "air-impregnated" paper. I do not see, however, that this invalidates our results. If the breakdown were purely a breakdown of air, then—making due allowance for variations in the machine—I should still expect the results to be much more uniform than they were. The reason we used air-impregnated rather than oil-impregnated or varnished

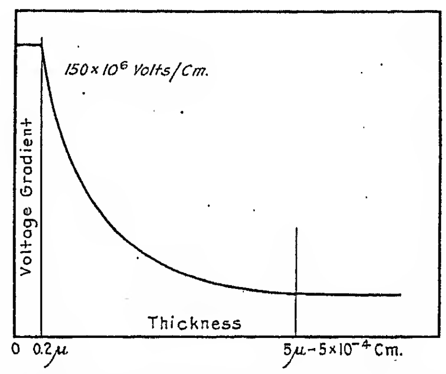

FIG. 2—BREAKDOWN GRADIENT OF VERY THIN SPECIMENS OF GLASS

paper was simply to keep the number of variables as small as possible. In any measurement of insulation, the number of variables is large at best. If oiled or varnished paper had been used, additional "unknowns," connected with the kind and condition of the impregnating substance, would have been introduced.

In the paper by Del Mar, Davidson, and Marvin,[2] the conflicting results obtained by different investigators have been pointed out. These discrepancies are undoubtedly due to the use of different materials by the various investigators. However, I think that the differences are partly due to the fact that some of these breakdowns occurred according to the thermal theories and some did not; that is, two investigators might test samples of the same material and might get entirely discordant results due to difference in thickness or temperature. One might get thermal breakdowns and the other might get ionization breakdowns.

That thickness and temperature have a vital effect on the mechanism of breakdown is shown by some recent work by a group of Russian physicists. I am referring to Joffé, Inge, Semenoff, Walther, and some others. These investigators have obtained a very good check on Rogowski's thermal theory with glass and with rock salt, provided the thicknesses were of the order of a millimeter or greater. In this case, if voltage gradient is plotted against temperature, the curve is very low near the melting point of the material and rises exponentially as the temperature is decreased (see Fig. 1 herewith). This is just as we would expect from Rogowski's theory. But the curve does not continue to go up indefinitely. At some temperature—150 deg. for glass—it makes a sudden break and becomes horizontal. Their tests have shown that it remains horizontal out to liquid-air temperatures.

Joffé has shown that the exponential part of the curve is due to thermal breakdowns, while the horizontal part is caused by ionization. In the latter part, he has shown that the breakdown gradient is

1. *Electric Strength of Solid and Liquid Dielectrics*, see p. 1049.

$$E = \frac{1}{u}\sqrt{\frac{2\,e\,P}{m}}$$

where u is the mobility of the ions, P is the ionization potential, and e and m are the charge and mass of the ion. This would indicate that the gradient at breakdown is independent of the thickness and temperature, provided the mobility stays constant.

It might seem that the horizontal part of the curve represented the maximum gradient obtainable, but some further work has shown that this is not the case. If gradient is plotted against thickness of the material (Fig. 2 herewith), for sheets less than 5 μ in thickness, the gradient goes up inversely as the thickness and rises to very high values. This again is supposed to be due to ionization by collision, but in this case the thickness is so small that there are insufficient ions to cause breakdown at the previous value (horizontal part of curve), and thus the gradient is higher than it would be for thicker materials.

Finally, a place is reached at about 0.2 μ, where the gradient is again a constant independent of thickness or temperature and having the immense value of 150 million volts per cm. Breakdown here is probably due to actual rupture of the molecules of the substance.

So, to summarize, these investigators have shown that there are at least three distinct mechanisms of breakdown, and that these different mechanisms apply in different cases.

The Electrical Resistivity of Insulating Materials†

BY HARVEY L. CURTIS*

Fellow, A. I. E. E.

Synopsis.—*A brief review is given of the literature on conduction through insulators. Every dielectric has a definite resistivity when the potential gradient is below a certain value, different for each substance. If the potential gradient is continually increased, a point is reached where an increase in voltage does not affect the current. This is called the saturation current. With still greater potential gradients, a point is reached where the current increases rapidly and breakdown soon results. All these phenomena of conduction are explainable as the movement of ions in an electric field.*

The resistivity of a dielectric depends on the number of ions in unit volume, on the charge on each ion, and on their mobility (velocity under unit potential gradient). The saturation current depends on the charge on each ion and on their rate of production. Breakdown is preceded by ionization by collision, which is determined by the ionization potential of the substance and the length of path of an ion.

The number of ions normally present in a dielectric depends not only upon the rate of producing them but also upon their rate of recombination. The rate of recombination is a constant of the material, but the rate of production may depend either upon outside agencies or inside forces. In gases, ions are generally produced by outside agencies, the important ones being rays from radioactive materials, X-rays and ultra X-rays. In liquids and solids, ions may be produced not only by the external agencies of rays and radiation, but also by the inside forces of solution and dissociation.

The ionic theory of conduction has been sufficiently developed to explain all the observed facts in the case of gases. Modifications and extensions are necessary, however, before all the experimental data on solids and liquids can be interpreted.

I. Introduction

An insulating material is defined as a material which either does not conduct an electric current or conducts it to a very limited extent only. There is, however, no definite lower limit of conductivity which sharply separates insulators from conductors. In fact, some substance on being subjected to a change in temperature will gradually and continually change from a state which would certainly be called conducting to one which, with equal certainty, would be called insulating. Since there is no sharp dividing line between insulators and conductors, it seems desirable to summarize, briefly, our knowledge of the process of electric conduction before attempting to apply it to the particular case of insulators. This paper will attempt to correlate our knowledge of the conductivity of insulators with the theories which have been put forward to explain the passage of electricity through conductors, and to point out the facts which require an extension of these theories in order that conduction through insulators may be explained.

Electricity is always associated with matter. Whenever there is a current of electricity, there is always a current of material particles. Electric currents can be divided into three classes depending upon the mass of the material particle associated with each fundamental electric charge. These are

1. Electronic conduction
2. Ionic conduction
3. Colloidal conduction.

In electronic conduction the moving electricity is associated only with the electrons. These are extremely small amounts of matter to which the elementary negative charge of electricity is inseparably bound. The most familiar example of electronic conduction is conduction through metals, although many interesting and important applications are found in vacuum tubes. Since electrons are all of the same mass and since the same current and hence the same number of electrons must pass every part of the circuit, there is no measurable transfer of matter in electronic conduction.

In ionic conduction the moving electricity is associated with a subdivision of a molecule, or in some cases, with such a subdivision to which a few molecules are attached. The most familiar example is conduction through electrolytes, although conduction through gases, through fused salts, and even through a number of solid substances is of this type. In this case there is always a transfer of matter, which can be detected at any surface of discontinuity in the materials which form the electric circuit.

In colloidal conduction, the electric current is carried by small masses of matter which are suspended in some inert medium. The electrical precipitation of smoke and dust by an electric current is an application of colloidal conduction.

While the three kinds of conduction are quite distinct, yet any two or even all three may take place simultaneously. As an example, it sometimes happens that when a solvent ionizes, one ion will consist of a single electron, while the positive ion will consist of all the rest of the molecule. Then when a difference of potential is applied, there is both electronic and ionic conduction. A complicated example of this is the Nernst filament at high temperatures, where both ions and electrons participate in carrying the electric current.

While the fundamental distinction between electronic and ionic conduction is the amount of matter carried by the current, yet there are other properties which are

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

more or less characteristic. The most important of these is the temperature coefficient of resistance. In metals, this is generally positive, while in electrolytes it is negative. Hence attempts are often made to determine whether a substance conducts electronically or ionically by measuring the temperature coefficient of resistance. At best, this is a very indirect method, and results so obtained require additional confirmation.

The phenomena connected with conduction through insulators depends on the state of the material; that is, whether it is a gas, a liquid, or a solid. The process is more complicated in liquids than in gases, and still more so in solids. Only in the case of gases has a fairly complete explanation of the experimental phenomena been deduced. Hence, in this paper there will be given a brief review of the facts and theories concerning conduction through gases; following this, a digest of some of the more important facts concerning conduction through liquids and solids including a correlation of these facts with the phenomena in gases.

II. Conduction Through Gases

The experimental facts concerning conduction through gases and the theoretical explanation of these facts have been treated in several different books.[1-2-3]

In all cases the authors correlate the experimental facts with the ionic theory. The following is a very brief résumé of this theory as applied to gases:

Consider two plane electrodes which are the opposite sides of a cubical box having a volume of one cu. cm. The other sides of the box are perfect insulators. This box is filled with air at atmospheric pressure. If a very small potential difference is applied to the plates for a short time, the current which flows is proportional to the applied potential difference. Hence, under these conditions, the air will obey Ohm's law. The resistance in the assumed case will be about 3×10^{15} ohms. If the potential difference between the plates is increased, the current will increase more slowly than the voltage. When the potential difference is in the neighborhood of 100 volts, the current has become about 10^{-18} amperes. This is called the saturation current, since it does not increase with a further increase in the potential difference. When, however, the potential difference is of the order of 30,000 volts, there is a very rapid change of current with voltage, leading up to the breakdown of the dielectric.

The facts as outlined above can readily be shown by the curve in Fig. 1. It is not feasible, however, to draw to a definite scale such a curve for air at atmospheric pressure, partly because there is considerable variation in the air and partly because if drawn to scale many of the interesting features would be entirely masked. For instance the section of the curve representing the saturation current would extend 300 times as far as the first part of the curve. When drawn to scale, the resistance at zero voltage can be determined from the tangent to the curve at the origin.

The explanation of the above phenomena is very satisfactorily given by supposing that there is some agency which is continually causing molecules of air to separate into positive and negative ions. These ions usually consist of an atom of either oxygen or nitrogen having a free positive or negative charge equal to the elemental electric charge. In atmospheric air under ordinary conditions the rate of ionization is about four or five ions per cu. cm. per sec. Since in a gas the molecules and ions are in violent agitation, the ions are likely to collide with each other. Whenever there is a collision between two ions having opposite charges, they may unite to form a molecule. When the number of molecules which are reunited each second is equal to the number ionized, a stationary condition has been reached. In normal air, there are always present about 700 or 800 ions per cu. cm. When a voltage is applied to the electrodes of the cubic box, the positive

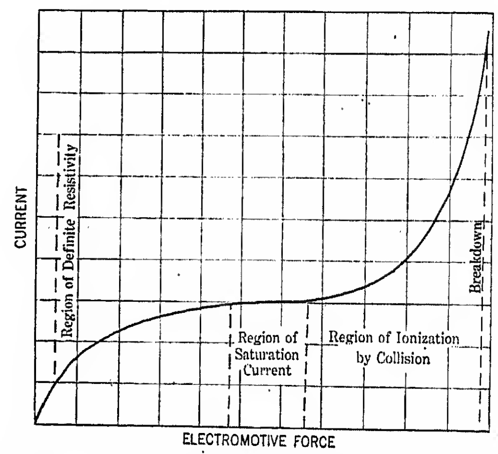

Fig. 1—The Current—Voltage Characteristics of a Gas

ions are attracted towards the negative electrode while the negative ions are attracted towards the positive electrode. On account of numerous collisions with molecules, however, the actual velocity of an ion towards the electrodes is only about one cm. per second if the potential difference of the electrodes of the box is one volt. Hence, if the voltage is very small, the conduction current will not, in a short time, appreciably alter the number or distribution of the electrons in the box. As the voltage is increased, however, the velocity of the ions also is increased. A point is soon reached where an ion is carried from the field almost as soon as formed. Now as the number of ions produced depends solely upon some external agency, an increase in voltage does not increase the current, since the current depends on the number of ions which reaches the electrodes. The saturation current is, then, the current which flows between two electrodes when the potential is sufficiently high so that practically every ion which is formed is carried to the electrodes without combining with another ion. Although the velocity

1–2–3. For references see Bibliography.

of the ions increases with increasing voltage, this only decreases the time required for the ions to travel from the place where they are formed to the electrodes, without changing the number which arrives every second.

When the voltage gradient becomes sufficiently high, the velocity of the ions becomes so great that, on colliding with a molecule of gas, the molecule will be broken into ions. Those ions, of which the negative may be a free electron, will then start towards the electrodes and may, in turn, ionize other molecules. Hence, the one ion which was produced by an external agency may be the cause of several ions reaching the electrodes. Therefore, as soon as the voltage applied to the terminals of the cubical box is so high that ions may have a velocity sufficient to produce ionization by collision with a molecule, the current increases rapidly with increasing voltage. This is shown in the latter part of the curve of Fig. 1. It leads rapidly to breakdown, a phenomenon not discussed in this paper.

There are a number of external agencies which will cause a gas to ionize. The best known are X-rays, the α, β, and γ, radiations from radioactive substances, ultra-violet light, and the ever-present radiations of unknown origin which might be called ultra X-rays. The ultra-violet light differs from the other agents in that it generally produces ionization only as it is absorbed by one of the electrodes. In order to simplify the discussion, this type of ionization will not be considered. The activity of the other ionizing agents can be determined from the number of ions produced in a gas, per cu. cm. per sec. As already indicated, the ever-present ultra X-rays produce some four or five ions per cu. cm. per second throughout the habitable volume of the earth's atmosphere. By sinking a small vessel filled with air some 50 or 60 ft. below the surface of a lake, Millikan and his co-workers[6] were able to protect this air from the effect of the ultra X-rays. Some ions were produced in this air, however, which could easily be explained by supposing that the metal of which the containing vessel was constructed bore minute traces of some radioactive substance. While man has never had a mass of gas in which ions were not produced, yet it is possible that under normal condition all ionization of gases is caused by some outside agency.

By using X-rays or rays from radioactive materials, the rate of production of ions can be made as great as a thousand or more per cu. cm. per sec. These recombine rapidly, however, so that no appreciable part of the 10^{19} molecules in a cubic centimeter of air is ever ionized at one time.

In order to develop equations from which the current through a gas can be determined from the applied voltage, the following constants must be known:

Let

q = number of ions produced per cu. cm. per sec. by the ionizing agent.

e = elemental electric charge (1.591×10^{-19} coulombs.)

k_+ = mobility of the positive ions; *i. e.*, the velocity in cm. per sec. when the potential gradient is one volt per cm.

k_- = mobility of the negative ions.

α = recombination coefficient.

δ = ionizing potential; *i. e.*, the potential difference through which an electron must be allowed to accelerate in order to acquire enough energy to ionize a molecule.

If n is the number of positive ions per cu. cm. of gas at a time t, there will also be n negative ions. Now the rate of increase of ions must equal the number of ions produced minus the number of recombinations. But since the chance of a given positive ion colliding with a negative ion is in direct proportion to the number of negative ions, the number of recombinations is proportional to the square of the number of ions. Hence

$$\frac{d\,n}{d\,t} = q - \alpha\, n^2 \tag{1}$$

This equation holds when there is no applied electromotive force. If this condition persists for some time, an equilibrium condition is reached, when $\frac{d\,n}{d\,t} = 0$. Then

$$n = \sqrt{\frac{q}{\alpha}} \tag{2}$$

It is this condition which exists in air under normal conditions.

With a very low potential difference between the electrodes, the number of ions which reaches them depends on the total number of ions in the field and on the velocity of the ions. Hence the conductivity λ is given by the equation

$$\lambda = n\, e\,(k_+ + k_-) = e\,(k_+ + k_-)\sqrt{\frac{q}{\alpha}} \tag{3}$$

The resistivity ρ is the reciprocal of λ. Hence the resistivity of a gas which has been exposed to an ionizing agent for a sufficiently long time for a stable condition to be reached depends on three constants of the gas; namely, the velocity of the positive ion, that of the negative ion, and the recombination coefficient.

The values of these constants for a few of the common gases are given in Table I. While the mobilities are quite different in different gases, yet there is relatively little difference between the positive and negative ions in the same gas. Also the recombination coefficient varies but little for the more permanent gases.

The saturation current S depends only upon the rate of ionization and the volume V of gas between the electrodes. It is represented by the equation

$$S = e\,q\,V \tag{4}$$

TABLE I
IONIZATION CONSTANTS OF GASES

Gas	Mobility of positive ion k_+ $\frac{cm.}{sec.} / \frac{volt}{cm.}$	Mobility of negative ion k_- $\frac{cm.}{sec.} / \frac{volt}{cm.}$	Recombination coefficient α
Hydrogen	6.	7.5	1.4×10^{-6}
Helium	5.	6.	....
Oxygen	1.3	1.8	1.6×10^{-6}
Nitrogen	1.3	1.8	1.6×10^{-6}
Carbon dioxide	0.8	0.9	1.6×10^{-6}
Carbon monoxide	1.1	1.1	0.9×10^{-6}

This does not contain any constant of the gas, but depends entirely upon the activity of the ionizing agent and the volume of the gas from which the ions can be captured by the applied electromotive force.

The ions, in their passage towards an electrode, collide at frequent intervals with a molecule. If, after a collision, the velocity of the ion should be zero, then at the next collision the energy which this ion has acquired is $e \overline{V} l$, where $\overline{V}$ is the potential gradient and l the distance it has traveled. To understand what effect this collision will have on the molecule struck, it is desirable to consider the analogous case of an electron colliding with an atom.

Experiments on gases at low pressures have shown that when an electron collides with an atom, the atom will be ionized only if the kinetic energy of the electron is greater than a certain critical value. The electron will normally obtain its kinetic energy by accelerating in an electrostatic field. Starting from rest, the kinetic energy of the electron at any instant is $e V$, where e is the charge upon the electron and V is the potential difference between the starting point and the point under consideration. The value of V, which is just sufficient to give to the electron enough energy to ionize an atom, is called the ionizing potential. Values of the ionizing potential are known for the atoms of most gases.

Likewise a molecule will be ionized by collision with an ion or electron, only if the velocity of the latter is sufficiently high. Since the velocity at impact depends not only upon the potential gradient but also upon the length of path between collisions, the voltage at which ionization by collision will begin increases almost in direct ratio with the pressure.

Our knowledge of conduction through gases at normal pressure, when the applied voltage approaches that which produces breakdown, is very incomplete. There is sufficient evidence to show that the rapid increase of current is the result of ionization by collision. It is not as yet possible, however, to formulate the laws under which it acts.

III. Conduction Through Liquid Dielectrics

The current is carried through most liquid dielectrics by ions. Hence most investigators have attempted to explain conduction through such substances by applying to them the same laws as hold for gases. The discussion of conduction in liquid dielectrics, therefore, centers around the production of ions, their mobility, and recombination.

Ions in a liquid dielectric may result from ionization of the dielectric itself, as is generally the case with a gas, or they may come from the ionization of substances dissolved in the liquid. The same external agencies that cause ionization of a gas will produce ionization in a liquid. In addition to these external agencies, the liquid may ionize spontaneously and ionization is often produced by some physical or chemical action between the liquid and a substance dissolved in it. The first is called ionization by dissociation; the second ionization by solution. As very minute amounts of a dissolved substance may produce a relatively large number of ions, impurities which can be removed only with difficulty often produce more ions in a liquid than is produced by a relatively intense external ionizing agent.

There is some evidence that all liquids are ionized by ever present ultra X-rays. In hexane the number of ions produced per cu. cm. per sec. is nearly fifty times as great as in air[25]. In most liquids the effect is masked by the effects of other ionizing agents.

X-rays and the rays from radioactive substances produce ionization in all liquids that have been examined. The effectiveness of a given ray is different in different liquids. For example, Jaffé[34] found that for hexane the ratio of ionization compared to air is about 1/1000 for α-rays but about 1/10 for β-rays. Also Greinacher[27] found that the number of ions produced by a given beam of α-rays was twice as large in paraffin oil as in petroleum ether.

The rate of recombination of ions in liquids is much less rapid than in gases. The few values of the recombination coefficient that have been determined[26] lie between 10^{-10} and 10^{-13}, or of the order of one millionth of that of gases.

The mobility of ions in a liquid is much less than in a gas. Values for a few liquids are given in Table II.

These values are of the same order of magnitude as the mobilities of ions in electrolytic solutions. There is a large increase in mobility with temperature, as is also the case with electrolytes.

No values of the ionization potential of a liquid molecule are available.

TABLE II
IONIZATION CONSTANTS OF LIQUIDS

Liquid	Average mobility of positive and negative ions—k $\frac{cm.}{sec.} / \frac{volt}{cm.}$	Recombination coefficient	Authority
Petroleum ether	500×10^{-6}	35×10^{-12}	26
Vaseline oil	5×10^{-6}	4×10^{-12}	26
Toluol	0.2×10^{-6}	....	17
Carbon tetrachloride	240×10^{-6}	....	33
Paraffin (60 deg.)	1600×10^{-6}	....	49
Electrolytic solutions in water	3000 to 300 $\times 10^{-6}$	....	17

According to most investigators, the current which flows between two electrodes immersed in a liquid and maintained at a constant potential difference is determined by the differential equation

$$\frac{d\,n}{d\,t} = q - \alpha\, n^2 - s \qquad (5)$$

where

n = the total number of ions at time t

q = the rate of production of ions

α = the coefficient of recombination

s = the rate at which ions reach the electrode—proportional to the current

If the ions are uniformly distributed through the liquid

$$s = \beta\, n \qquad (6)$$

where β is a constant which among other things involves the mobility of the ions. Substituting this in (5) and separating the variables

$$\frac{d\,n}{q - \beta\, n - \alpha\, n^2} = d\,t \qquad (7)$$

Integrating

$$\log n \frac{2\,\alpha\, n + \beta + \sqrt{4\,\alpha\, q + \beta^2}}{2\,\alpha\, n + \beta - \sqrt{4\,\alpha\, q + \beta^2}} = t\,\sqrt{4\,\alpha\, q + \beta^2} + C \qquad (8)$$

This shows that n is an exponential function of t. It follows that s, the current between the electrodes, decreases as the time during which the electromotive force is applied increases. This same solution holds in the case of gases, but in them, the mobility is so great that equilibrium is reached in less time than that required for the measuring instrument to reach a steady condition. With liquids, however, the mobility is much less and the decrease of the current with time can be readily observed. Most observers have made readings one minute after the application of the electromotive force. During this time, the current will in most cases become stationary.

The conductivity λ of a liquid is given in terms of ionic constants by an equation similar to that for a gas, namely:

$$\lambda = 2\, n\, e\, k \qquad (9)$$

where

λ = the conductivity

e = the charge on an ion

n = the number of ions per cubic centimeter in the stationary state

k = the average mobility of the positive and negative ions.

As the mobility of ions in liquids is from a thousand to a million times less than the mobility in gases, the conductivity for a given concentration of ions is proportionally less or the resistivity proportionally greater. The number of ions, however, is generally so much greater in liquids than in gases that the resistivity of many liquids is less than that of gases under similar conditions.

As the potential gradient in a liquid is increased, the current approaches saturation in the same way as in a gas. Difficulties, however, are frequently encountered in the experimental determination of the saturation current of a liquid. As an example, when the number of ions is small, it is probable that most of them will be caused by the solution of traces of impurities. Before the current becomes stationary, many of the ions of the impurities will go to the electrodes, thus removing from the liquid the cause of the ionization. Hence, before the saturation current can be reached, the fundamental character of the liquid has changed.

As a second example, when the liquid contains a large number of ions which have been produced by any cause whatever, an ion concentration occurs near the electrodes before the current becomes stationary. The potential gradient in the region of this concentration is reduced so that the gradient near the electrodes is less than at a point midway between them. On account of this reduced gradient, the velocity of the ions towards the electrodes is reduced and the chance for recombination increased. These two examples show that the experimental difficulties of determining the saturation current in a liquid are much greater than in the case of a gas.

Another difficulty in connection with the determination of the saturation current in a liquid is that ionization by collision may start before the potential gradient is sufficiently high to produce saturation. When this is the case, no true saturation current occurs. This phase of conduction in liquids, however, has received very little systematic investigation.

Much larger potential gradients can be applied to liquids without appreciably affecting the conductivity than can be applied to gases. Thus, in most liquids, the conductivity obeys Ohm's law if the potential gradient is less than three or four hundred volts per cm., whereas in a gas it must be less than one volt per centimeter. Where higher potentials are applied the current does not increase as rapidly as the potential. For example Jaffe[23] found for several liquids that if the potential gradient were between 500 and 3000 volts per cm.

$$I = a + c\,E \qquad (10)$$

where a and c are experimental constants.

The resistivity of most liquids decreases with increasing temperature. This is largely caused[16] by a change in mobility, as the number of ions is nearly independent of temperature. Attempts to correlate[11] the resistivity of a liquid with its viscosity, however, have been unsuccessful.

The above explanation of the passage of electricity through liquid dielectrics is based on the assumption that the ionic laws of gases can be applied to liquids. Some investigators are of the opinion that these laws will require some modification before a complete

explanation can be given. Von Schweidler[17] has proposed two modifications; the first suggests that equation (5), which gives the rate of increase of ions, should be

$$\frac{d\,n}{d\,t} = f\,(n) - s \tag{11}$$

where $f\,(n)$ is an unknown function. The reason for this suggestion is that the solution of equation (5) shows the current to be proportional to the square of the conductivity, while experimentally the current is found to be proportional to the conductivity with a fractional exponent. The second suggestion is that, in many liquids, several different kinds of ions exist, each having a different mobility. When an electromotive force is applied, the kinds of ions having the higher mobilities reach the electrodes more rapidly than those with the low mobilities. As a result, the average mobility of the ions which are left decreases as the time of application of the electromotive force increases. This agrees with the results of tests on several liquids.

IV. Conduction Through Solid Dielectrics

Conduction in solid dielectrics is difficult to distinguish from the phenomena of absorption and residual charge. In this respect, solids are entirely different from liquids and gases in which these phenomena are seldom, if ever, present. Also, electrons play a more important part in conduction through solids than liquids or gases. Ionic conduction, however, is much more common than electronic. Hence in the discussion it will be considered that conduction in solids is caused by ions, the electron being considered the smallest possible ion.

Although the external agencies which cause ionization in solids are the same as in liquids or gases,—namely, electromagnetic radiations and rays from radioactive substances,—the effectiveness of the different agencies is quite different. The α and β rays from radioactive substances ionize some, and perhaps all, solid dielectrics. Also it seems probable that for any given wave length of electromagnetic radiation some solid can be found which will be ionized by it. Moreover there is a number of solids which are ionized by a very wide range of wavelengths. Some illustrations of these facts are cited in the following.

There are few data concerning the ionization of solids by the ever-present ultra X-rays. It may, however, be because of these rays that no substance is known which has infinite resistivity. Sulphur, paraffin, and quartz are ionized by both λ-rays and X-rays. The ionization of selenium by X-rays is so definite that some roentgenologists have proposed using this material to measure dosage. Quartz is ionized by ultra-violet radiation. The visible part of the spectrum produces ionization in a number of substances, the most familiar being sulphur and selenium. In fact, one form of selenium is ionized not only by all of the visible spectrum, but also by the infra red rays.

In addition to the external agencies which produce ionization, substances dissolved in a dielectric may produce it. Familiar examples are water dissolved in rubber and alcohol dissolved in shellac. The influence of minute quantities of a dissolved substance is often very marked. Hence, there is often great difficulty in ascertaining the true resistivity of a substance since it is exceedingly difficult to remove the last traces of an impurity. Some dielectrics ionize spontaneously. There is some interaction between molecules so that ions are always present. With such dielectrics an increase in temperature frequently increases the number of ions in a very marked degree. Glass is an example of such a dielectric.

In general, the mobility of ions in a solid are less even than in a liquid. The values given in Table III however, are not entirely characteristic. In case of light-sensitive selenium, the negative ions are single electrons, the mobility of which is probably quite high, while that of the positive ion is negligibly small in comparison. In this case the conduction is electronic.

TABLE III
IONIC CONSTANTS OF SOLIDS

Substance	Average mobility of ions $\frac{\text{cm.}}{\text{sec.}} \Big/ \frac{\text{volts}}{\text{cm.}}$	Recombination coefficient	Authority
Paraffin...........	0.14×10^{-6}	....	49

On the other hand the mobility of the positive ions is sometimes high relative to that of the negative. This is the case with some kinds of glass. In such glasses the positive ion can be replaced by other positive ions which are carried into the glass by the current. Many similar cases are known. These examples show that in solids, the difference in mobility of the positive and negative ions may be so great that the conductivity is entirely dependent on the ions having the highest mobility, and not, as is usually the case, in liquids and gases, on the average mobility of the two kinds.

The mobility of the ions in a substance frequently increases rapidly with the temperature. In crystalline quartz[67] the mobility at 100 deg. cent. is about 200 times that at 0 deg., while in calcite it is more than 10,000 times as much at the higher temperature. In rock-salt, on the other hand, there is little if any change in mobility with temperature.

There are few quantitative data on the coefficient of recombination of ions in solids. There is, however, a considerable amount of qualitative information. For instance, it is known that in light-sensitive selenium, practically all the ions are recombined in two or three seconds after removal to the dark. The recombination in crystalline quartz is much slower. At room temperature several months or even years are required before a piece of ionized quartz will reach an equilibrium condition. These examples doubtless represent extremes in regard to recombination.

There are practically no data concerning the ionization potential of the molecules of a solid. There are, however, sufficient data to show that ionization by collision occurs in solids although it is often difficult to separate it from other phenomena which are present when high voltages are applied to a solid dielectric.

It is probable that the law of ionic equilibrium given in equations (**1**) and (**5**) will require modification even in the case of homogeneous solids. At present, however, it furnishes the only accepted basis from which to discuss the observational data. On this basis materials should have a definite resistivity when the applied voltage is low and the time of application long, and should reach, or at least approach, a saturation curve when the voltage is sufficiently increased. Both conditions have been observed.

To conform with this law, conduction current in a solid must decrease with time according to an exponential law, as has been shown to be the case for a liquid. The measurement of the conduction current in solids, however, is complicated by the fact that the absorption current also decreases with the time in much the same way. There is no known method of distinguishing between these currents. In some materials, however, the conduction current is so great that the absorption current can be neglected. Moreover, in all materials, the absorption current tends towards zero, while the conduction current tends towards a fixed value, provided the ionization remains constant. The ionization in solids is generally due to conditions within the material. Often these conditions are disturbed by the passage of the current, so that the current at infinite time does not represent the true conduction current. It follows that no entirely satisfactory procedure can be established. The commercial practise of reading the current at the end of one minute after the potential has been applied appears to be as good a one as any that can be suggested.

The saturation current in solids has occasionally been observed. An interesting case is reported by Jaffe[67], who found that the current in crystalline quartz was independent of the applied potential if the potential gradient was between 10,000 and 50,000 volts per centimeter, and that a steady condition was reached in three seconds after the application of the voltage.

The change of resistivity with temperature depends both on the change in the number of ions and on the change in their mobility. In some solids the temperature coefficient is small and positive, but in most solids it is large and negative. Rasch and Hinrichsen[44] found that, in glass, the change in resistance R could be represented by the formula

$$\log R = \frac{A}{T} + B \qquad \textbf{(12)}$$

where T is the absolute temperature and A and B are constants. This same law has been found to fit a number of substances. As the dissociation of gases into ions (a subject not treated in this paper) obeys the same law, the conclusion is often drawn that the cause of the negative temperature coefficient in such solids is the dissociation of molecules into ions caused by the increase in temperature. This law, however, holds with some solids in which the change in resistance with temperature is known to be caused—at least in part—by the increase in mobility of the ions. Hence the dissociation coefficient can be determined from the temperature coefficient only when there is no change of mobility with temperature.

The above deductions concerning homogeneous dielectrics apply to the individual components of a heterogeneous dielectric. The most interesting form of such dielectrics is one composed of layers perpendicular to the direction of current flow. A consideration of this type leads immediately to the question of absorption, a subject which has been treated in another paper* of this series.

V. Conduction over the Surface of Solid Insulators

Gases or vapors are often condensed to a liquid form on the surface of a solid with which they are in contact. If the angle of contact between the solid and liquid is greater than 90 deg., the liquid collects in droplets; but if the angle is less than 90 deg., the liquid spreads, in a film, over the surface of the solid. In one case, the presence of the liquid has little effect on the insulation of electrodes fastened to the solid, but in the other, the current which flows from one electrode to another *through the solid* is often much less than the current which flows through the condensed liquid.

The condensation of water vapor from the air on solid surfaces is a familiar example of surface condensation. With waxes, the condensed water forms into droplets, but with most materials, it spreads in a film over the surface. If the film is formed on the clean surface of an insoluble material, like quartz or amber, the water is very pure. Since pure water is a poor conductor, the film may not carry an appreciable current. The slightest trace of a soluble salt however, will so greatly increase the conductivity of a film that the current through it may be much larger than that through the solid itself. Many solids, such as glass and porcelain, are sufficiently soluble so that films deposited on them are always conducting. The presence of delequiscent salts very greatly increases the amount of condensed water. In all cases, the amount of condensed water increases as a rather large *power* of the relative humidity.

Surface films play an important part in conductivity through porous materials, such as unglazed porcelain, marble, and slate. The pores extend deep into the material. If a specimen is exposed to a humid atmosphere, the pores become lined with a film of water, which

*J. B. Whitehead: *Dielectric Absorption and Theories of Dielectric Behavior*, A. I. E. E. Trans., Vol. 45, 1926, Mar., p. 102.

may have a conductivity many thousands of times greater than that of the material itself. The result is a decrease in the volume resistivity of the material. Evershed considers that conduction phenomena in fibrous materials is associated with surface films in the pores of the material. However, he makes the further assumption that the thickness of the film decreases as the applied voltage is increased. This explains the increase of resistance with increasing voltage which is shown by such materials.

VI. Conclusion

This paper includes only a small part of the facts which are known concerning conduction through insulators. There is every reason to believe that all the known facts can be explained by the ionic theory, the main tenets of which are herein set forth. The details of this theory are sufficiently developed to explain practically all the experimental facts in connection with the passage of electricity through gases. The same cannot be said in regard to liquids and solids. Here the phenomena are more complex and the experimental data more meager. A complete explanation must await further investigation.

Discussion

F. M. Clark: With regard to Dr. Curtis' paper, I do want to emphasize the type of conduction which he calls colloidal conduction. I think that this is a type which we will have to recognize and consider in more detail than we have. When you consider that almost all of our insulations are colloidal in nature, if not true colloids, you can see the significance of that type of conduction. I recognize that colloidal conduction is similar in many respects to electrolytic conduction. However, it owes its origin to larger charged masses and may occur in mediums where electrolytic conduction would be least expected.

Dr. Curtis discusses the conduction over the surface of solid insulators. The effect of water-vapor condensation is cited and its importance discussed. Although the author illustrates the effect on inorganic materials such as quartz and porcelain, it should not be overlooked that conductivity in fibrous materials appears to be closely related to the cases given. Our researches at Pittsfield have not been entirely completed, but we have already obtained considerable evidence that the quantity of water contained in an oil-treated paper, while important, is not the sole factor determining the a-c. and d-c. conductivity. It appears that the effect produced depends very largely on whether the water vapor present is absorbed on the surface of the paper fibers or whether it be held within the fiber wall.

Electric Strength of Solid and Liquid Dielectrics*

BY W. A. DEL MAR†, Chairman, Fellow, A. I. E. E.
W. F. DAVIDSON‡, Fellow, A. I. E. E.
and R. H. MARVIN§ Associate, A. I. E. E.

Synopsis.—*This paper was prepared by a subcommittee of the Committee on Electrical Insulation of the Division of Engineering and Industrial Research of the National Research Council. The general purpose of the committee is to foster research on dielectrics and its initial activities have been confined to the preparation of a series of summaries of the published literature on this subject.*

The subcommittee which presents this paper is the second one to report, having been preceded by a paper on dielectric absorption and theories of dielectric behavior, by Chairman J. B. Whitehead, which was published by the A. I. E. E. in 1926.

The second paper under the auspices of the committee was inspired by the first one, and was an original exposition of Clerk Maxwell's theory of the double layer dielectric, by Professor Murnaghan, published by the A. I. E. E. in 1927.

The present paper, like the first, is a summary of existing literature which, it is hoped, will afford a starting point for original research in many directions. It is hoped that the discussion by the Institute will bring out obscure phenomena and new interpretations of the data reviewed. The report starts with a consideration of the general subject of instability in electrical circuits, and an explanation of instability in the case of dielectrics, in terms of a stress and strain characteristic. This is followed by a discussion of distribution of stress and strain in non-uniform fields, and their relation to breakdown. The reversible and non-reversible phenomena of dielectric failure are considered, the former in relation to the electron theory and the latter in relation to the pyroelectric theory, and the bearing of both upon the time-voltage relation is indicated.

The latter part of the report is devoted to the relation of breakdown voltage to various factors, such as insulation thickness, insulation area, the electrode form, heterogeneity, temperature, rate of voltage, variation, pressure, etc. Final conclusions are given which summarize in a few words the present state of the art, as it may be judged from published data.

General

FARADAY seems to have been the first to use the term "dielectric" to distinguish certain classes of materials by their electrical properties and he defined dielectrics as all bodies whose insulating value is such that when they are placed between two conductors at different potentials the electromotive force acting on them does not immediately distribute their electricity so as to reduce the potential to a constant value. It was not until considerably later, however, that we find recognition of the fact that if the potential difference across a dielectric is sufficiently increased, failure will occur; or, to state the matter in another way, the current will increase with a decrease of voltage and conditions will be unstable. The stress at which this unstable condition begins is called the dielectric strength of the material, but it depends on many factors, as will be discussed later in this paper, and is by no means an exact physical constant.

At the present time, it is proposed to discuss the literature in regard to the dielectric strength of solids and liquids. It should be recognized that liquids occupy a ground between solids and gases and may be treated, with equal reason, in connection with the behavior of gases or with the behavior of solids. In some respects they will behave more like one than the other but in general there is but little to choose between one grouping or the other. The methods for examining solids and liquids are in general different and this will introduce several questions which will need answer before we can arrive at definite conclusions.

An examination of the literature discloses the fact that a large number of solid dielectrics has been investigated by several workers but the range of liquids examined is far more restricted. This is not surprising, however, when it is recognized that the majority of our commercial insulating materials are solids and comprise such varied materials as glass, fiber, wood, moulded compounds, mica, sulphur, paraffin, rubber, paper, and porcelain, while in the list of liquids we find only a few oils, chiefly distilled from petroleum crudes, and usually classified under the general type of transformer oil. Many liquids, such as benzine, kerosene, toluol, xylol, and carbon tetrachloride, are good dielectrics but seem to have found little or no commercial use and hence not to have gained the interest of various investigators.

Instability

It is helpful to consider dielectric failure as the phenomenon of instability which exists when the voltage across the dielectric has been increased to a certain critical value beyond which the current increases more or less in unpredictable ways while the voltage tends to fall. Well-known examples of such cases are associated with arcs without ballast resistors, overloaded reactors, transformers, and series wound generators.

There is always difficulty in assigning credit for the first presentation of a line of thought, for when a number of men are working simultaneously on the same problem they are inevitably led into similar trains of thought. Perhaps the first clear statement connecting the failure of dielectrics with the general phenomenon of instability is that of Steinmetz[1] in 1923 when he said that "the

view is gaining ground that the mechanism of dielectric failure is a phenomenon of the instability of the so-called constants of the material."

Stress-Strain Characteristic

It was, however, a research by K. W. Wagner[2], initiated in 1914, interrupted by the war, and completed in 1919, which gave the first quantitative data on which to base a satisfactory theory. This physicist was the first to ascertain the volt-ampere characteristic of a solid dielectric, and he showed that the characteristic curve consists of a straight line corresponding to Ohm's Law, a curve which becomes vertical, *i. e.*, parallel to the current axis, and finally slopes backward, corresponding to a rising current with falling voltage, as shown in Fig. 1.

It is not difficult to obtain the first two parts experimentally, but the third part corresponds with a condition of unstable equilibrium and is normally passed at such an immense speed that it cannot be observed unless special precautions are taken.

Wagner succeeded in plotting the entire curve by

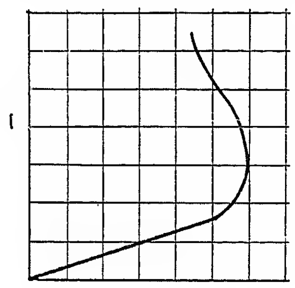

Fig. 1

using an electrode of such high resistance that the circuit, as a whole, had stable characteristics, *i. e.*, current rising with voltage, and thus stabilized the dielectric in the same way that a ballast resistance is used to stabilize an arc. Current and voltage readings were first taken with the electrodes in contact with one another, and then with the dielectric between. The difference in voltage for the same current, in the two cases, was the voltage across the dielectric corresponding to this current. The general form of these characteristics was verified in 1921 by J. C. Schrader[3] who used a hot cathode rectifier in series with the dielectric, to restrain the current.

In the same year, H. H. Poole[4], using the same method as Schrader, found that the conductivity of certain dielectrics rises with the potential gradient, the logarithm of the conductivity being nearly a linear function of the gradient.

In 1925, H. Gabler[5], also using a thermionic valve for ballast, obtained experimental curves of the same general form.

In all these tests, direct current was used. Corresponding data for alternating current have not yet been obtained, indicating a fruitful field for research.

No work appears to have been done on liquids in an effort to determine the volt-ampere characteristic although Gunther-Schulze[6] made determinations of dielectric conductivity over a considerable range of stresses and found a tendency for the current to decrease with increase of voltage. This may be explained by consideration of the fact that the voltage was gradually increased and this gave additional time for impurities, which apparently constitute a considerable number of carriers, to be swept out of the field.

The shape of the curve for solids has been explained by Wagner on the basis of the negative temperature coefficient of resistivity characteristic of all dielectrics and by Peaslee as due to ionic migration. These theories are explained at greater length, below.

One of the consequences of the form of volt-ampere characteristic is that an unequally stressed dielectric, by virtue of the different current densities in its parts, may have in one place a rising current density and in another a falling current density, with increase of voltage. This was expressed by W. D. A. Peaslee[7], in 1922, by saying that a dielectric, if unequally stressed, may have a positive value of $\frac{dI}{dE}$ in one part, and a negative value in another, but failure will not occur until the total $\frac{dI}{dE}$ becomes infinite. An important part of Peaslee's contribution is the interpretation of Wagner's volt-ampere curve in terms of voltage and current density.

Dielectric Overstressed Without Injury

That part of the dielectric which has $\frac{dI}{dE}$ negative is overstressed, that is, it would fail but for the stabilizing action of the remainder of the insulation, which acts as a ballast resistor.

Wagner, working simultaneously along similar lines, described an experiment on a dielectric which had been unequally stressed for a short time so that one part was stressed above the point where $\frac{dI}{dE} = \infty$, and he showed that this over-stressed part, when subsequently tested alone, had lost none of its dielectric strength.

Stresses in a Dielectric with Non-Uniform Field

The next step toward putting the behavior of dielectrics upon a quantitative basis was taken by P. L. Hoover[8] who showed that the characteristic curve could be expressed in terms of potential gradient and current density and that therefore if the current density be plotted for the various parts of an unequally stressed dielectric, the corresponding potential gradients and

values of $\frac{dI}{dE}$ can be plotted from the characteristic curve and the behavior of the dielectric deduced therefrom. In other words, if the current densities at various points be computed from the resistivity and geometrical configuration, the corresponding stresses may be derived from the characteristic curve.

Thus, in a dielectric between co-axial cylinders, *i. e.*, a single-conductor cable, if the same current be assumed to flow in all parts of the circuit, the current density must decrease radially, and may therefore be represented by an hyperbola, such as A in Fig.2. Referring

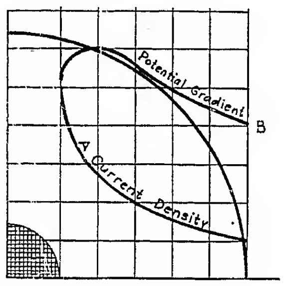

FIG. 2

now to the volt-ampere characteristic, Fig. 1, as each value of current density corresponds with a definite potential gradient, a curve representing the potential gradient at all radii may be plotted, as shown by the curve B in Fig. 2.

If the current density is increased, the maximum of curve B moves outward. In doing so, the area to the left of the maximum increases, while that to the right decreases. The curve is not symmetrical; hence there is a certain current at which the area enclosed by the curve is a maximum. But this area is the total voltage between cylinders. Hence there is a value of the total voltage E such that $\frac{dI}{dE} = \infty$. This will be the breakdown voltage.

Applied to solids, this theory gives results which accord better with the facts than the well-known theory published almost simultaneously in 1901 by M. O'Gorman[9] and E. Jona[10], according to which the unequally stressed dielectric between co-axial cylinders will begin to fail at the inner surface, the failure spreading outward from that point until rupture occurs. Important modifications of this theory were published by W. I. Middleton, C. L. Dawes, and C. L. Davis[11] in 1922, and R. J. Wiseman[12] in 1923.

Considering this theory in its original form, if certain assumptions are made, it may be shown that

$$g = \frac{E}{x \log_e \frac{R}{r}}$$

where

g is the electric stress at any point distant x from the axis of the cylinders,

R is the inner radius of the outer cylinder,

r is the outer radius of the inner cylinder,

E is the potential difference between cylinders.

By this formula the maximum stress is always at the inner conductor surface, *i. e.*, with $x = r$, and the minimum stress at the outer conductor surface, *i. e.*, with $x = R$.

The assumptions which are made in deriving the above formula are that the dielectric has uniform resistivity and specific capacity in all directions, and that the resistivity and specific capacity do not alter with stress.

The first two assumptions are often unjustifiable, and the third is certainly wrong for most materials at stresses approaching failure. Since it is at these high stresses that the formula finds its principal application, it is evidently basically unsound, except for a few materials which may have characteristic curves without any maximum point.

So flagrant were the observed departures from the consequences of the logarithmic formula that in 1920, F. Fernie[13] suggested that failure of insulation in a single-conductor cable occurs when a certain value of the minimum stress is attained. This theory was ably criticized in 1922 by D. M. Simons[14] who showed that experimental data are as consistent with failure taken to occur at constant average stress as at constant minimum stress.

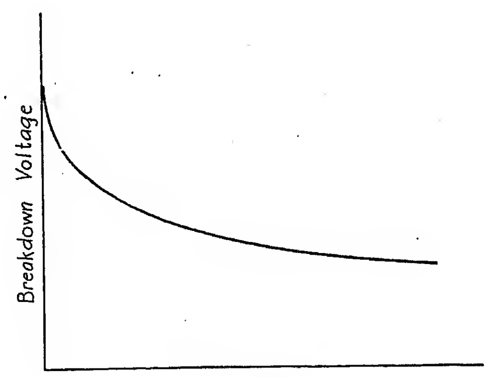

FIG. 3

It is now fairly evident that the maximum stress determines failure, but that this stress cannot be calculated by the ordinary formulas which neglect the peculiar shape of the volt-ampere characteristic at stresses approaching failure.

Hendricks[15] mentions the results of tests on transformer oil using concentric cylindrical electrodes of different sizes, and finds that the breakdown strength as calculated on the maximum stress theory is not constant. On the other hand, Peek[16], as a result of similar tests, comes to the conclusion that there is a

definite maximum stress, 36 kv. per cm., which is the value at which an increase in conductivity results from ionization by collision.

Another factor which may be of considerable importance in some cases and that seems to have been generally overlooked in the computation of stresses, although it is made the basis for many explanations of the phenomenon of absorption, is the combined influence of resistivity and specific inductive capacity on distribution of stress. That this may be an important influence is indicated by the different values of dielectric strength obtained with direct potentials and alternating potentials of different wave form and frequency, as discussed later in this report.

Time—Voltage Relation

Thus far we have dealt exclusively with so called momentary stresses, *i. e.*, those which are not maintained sufficiently long to produce chemical deterioration of the insulation.

The relation between the breakdown voltage of a dielectric and the time of application of the voltage is of the character shown in Fig. 3, *i. e.*, the breakdown voltage for short periods is high and falls off rapidly with increasing time, whereas that for long periods is comparatively low and changes little with the time. This was clearly shown in 1907 by H. W. Tobey[17].

The general form of the curve suggests two influences at work, one corresponding to instantaneous action and the other to prolonged action, the intervening periods corresponding to a combination of the two. This idea is discussed at greater length under "Irreversible Deterioration."

It has been shown by F. W. Peek[16,18] and also by V. M. Montsinger[19] that experimentally determined time-voltage curves using solid insulations may be approximated by the following empirical formula:

$$E = A + B \, . \, T^{-4}$$

where E is the voltage that the insulation will stand for a time T, and A and B are constants. No rational basis for this formula has been found, and recent work suggests that the curve may not be continuous, but may have a break, with a different law for each side of the break.

Data presented by Farmer[20] as a result of tests on oil impregnated paper insulated cable may be expressed by the equation derived by Montsinger, except that the exponent of the time term is 7 instead of 4. There seem to be clear limitations as to the range of stress over which this expression may be applied, however, and it evidently has but limited use; certainly there is no ground for assuming that it may be applied to materials other than the specific ones investigated.

Another aspect of the time-voltage relation was indicated by C. P. Steinmetz[1] in 1923, namely, the differing time-lag of various dielectrics. If two insulating materials are in parallel, the one which will fail under stress will depend upon the time of application of the voltage and upon the time-lag of electric strength of the two materials. Thus, under lightning conditions, transformer bushings may flash over without injury to the oil insulation, whereas on test, the oil insulation may puncture far below the voltage at which the bushings flash over.

Air has no appreciable time-lag, but a sphere-gap with high resistance in series has an appreciable time-lag, due to the time required to charge the capacity of the spheres over the resistance.

True liquids do not seem to be influenced by the time of application of the voltage although there is a time-lag for rapidly applied voltages and Peek[21] has found this lag to obey almost the same laws as he established for gases. Dieterle[22], in a series of tests with semi-fluid materials intended to determine the relations between the magnitude of continuously applied stress and the time to produce failure, obtained results similar to those already noted for solids although they are too few to permit establishing a mathematical expression.

Yet another angle to the time-voltage relation has to do with the effect of direct and alternating potentials and the influence of wave form and frequency in the latter case. These will be discussed in more detail later on in this report, but it should be pointed out that at the present time these factors have to do with the short-time part of the curve.

Pyroelectric Theory

Miles Walker[23], in 1912, was probably the first to call serious attention to the dielectric loss-temperature relation as a factor in dielectric failure. He was followed in 1917 by A. F. Bangs and H. C. Louis, and W. S. Clark and G. B. Shanklin[24], and in 1922 by D. W. Roper[25], all of whom dealt with average losses in relation to mass heating of cable dielectrics. At about this time C. P. Steinmetz and J. R. Hayden contributed ideas as to the general application of this theory and coined the name "pyroelectric theory."

K. W. Wagner[2] in 1922 went a step further by taking into account the well-known unevenness of dielectrics and considering the effects of a filament of higher dielectric loss or, as he expressed it, lower resistivity than the surrounding mass. He laid particular stress on the well-known fact that dielectrics, unlike metallic conductors, possess a negative temperature coefficient of resistivity; *i. e.*, their resistivity decreases with rising temperature. Hence, if a spot or filament of comparatively low resistivity exists in a dielectric, the extra $I^2 R$ loss which occurs in it will tend to raise its temperature, which in turn by decreasing the resistivity will increase the current and temperature, and so on accumulatively until failure occurs due to burning.

This theory was ingeniously developed by Wagner as a general theory of dielectric failure by assigning an empirical equation to the temperature-resistivity relation, and assuming arbitrarily a certain diameter for

the hot filament. The quantitative results obtained were later found to depend very largely upon the value assumed for this diameter. Morover, work by L. Dreyfus[26], H. Rochow[27], W. Rogowski[28], Von Karman[29], H. Gabler[5], and others, has shown that the theory, as developed by Wagner, is untenable, both from a theoretical standpoint and because it yields numerical data which are widely at variance with facts.

Wagner's theory considers only the effects of filaments of low resistivity. C. P. Steinmetz, in 1923, called attention to the effects of particles of high specific capacity, as follows:

> "A particle of higher specific capacity than the surrounding material will concentrate the lines of electric force toward itself, creating points or edges of excessive flux density at the 'poles' of the particle. The insulation would char at these points or edges, and the shape of the product of chemical decomposition would tend toward the form of a conducting needle, with excessive voltage gradients at its ends, gradually piercing the dielectric until final puncture occurs between the terminals. Thus in a laminated insulation, consisting of very many layers, a foreign particle in one of the layers, though originally forming only an insignificant part of the *total* thickness of the dielectric, may gradually but cumulatively, in the course of time, pierce and destroy the insulation by its electrostatic cutting edges, the average voltage gradients within the dielectric being still very low compared with the tested 'dielectric strength' of the material."

Thus unevenness of specific capacity, as well as of resistivity, is a factor in pyroelectric failure. Perhaps there are other factors which explain the phenomenon noted in 1910 by H. Osborne[30], namely, that when a solid dielectric is over-stressed, it is not disrupted uniformly, but is affected as if it had been pricked by a number of needle points.

The failure of Wagner's theory in a quantitative sense should not be interpreted as discrediting the general pyroelectric theory, as cumulative heating is undoubtedly a factor in many cases of dielectric failure. It is not that the theory must be discarded but that it must be amplified and made part of a more general and complete theory.

There seems to have been no attempt to apply the pyroelectric theory to liquids and indeed it is hard to see how this could be done since the existence of convection currents would tend to largely mask any of the detail phenomena assumed for solids.

Irreversible Deterioration

All solid dielectrics on which published data are available show some kind of permanent deterioration when exposed to stresses over a certain critical value. Thus, it was found by F. M. Clark[31] in 1925, that prolonged stresses permanently injure oil-impregnated paper insulation and that the injury is cumulative, even if the stresses be applied intermittently. Other experimenters have verified this conclusion and extended the rule to a wide range of materials. Clark also verified Wagner's observation that *momentary* overstressing produces no appreciable permanent injury.

The nature of the injury depends upon the material, and may be any of the following:

A. Direct effect of stresses,
   - a. Polymerization and condensation,
   - b. Redistribution of component materials according to specific capacity,
   - c. Change in surface tensions between component parts,

B. Indirect effect of stresses,
   - a. Thermal effects such as carbonization,
   - b. Chemical combinations such as oxidation,
   - c. Electrolytic effects.

An example of polymerization is the formation of the solid material provisionally known as "X", in mineral oils.

Redistribution of component materials according to specific capacity is exemplified by particles of cellulose in oil.

Change in surface tensions is one of the important factors in the failure of oil impregnated cables. In such composite insulations composed partly of solid and partly of liquid materials, an air or vacuous pocket may serve as a center of disturbance, and the liquid material, as observed by Dunsheath[32] in 1926, will be driven away from the pocket, thereby enlarging the latter. Such oil free spots would ultimately link together, and ionization would be established, leading to charring in dendritic or tree-like patterns. The projection of oil from places of high stress to those of low stress, in this case, is apparently due to an increase of surface tension between air and oil as compared to that between paper and oil.*

Many experimenters, such as A. P. M. Fleming and F. Johnston[33], in 1911, have found that where air is present and the voltage is high enough to create discharges, cellulose materials have their structure disintegrated; oils and gums are converted into various products. Some of these actions are thermal and others are chemical reactions, but all are cumulative and irreversible.

Little is known about electrolytic effects but they are under investigation in the case of glass.

The redistribution of moisture by endosmose may be a factor of some importance, as indicated by the work of S. Evershed[34] in 1914. Endosmose is a motion of films of water along the walls of an insulator, due to the water being electropositive to practically all solid insulating materials, and being, therefore, drawn through the pores of the solid toward their electronegative ends.

*It had been observed by several people [35] in 1924 that impregnated paper cable insulation fails as the result of surface discharges rather than punctures.

The alignment of threads of moisture has the effect of partially short-circuiting the dielectric.

At this time it seems opportune to reinterpret the time-voltage curve in terms of the Steinmetz, Dunsheath, and similar effects. It has been observed that the shape of this curve suggests two influences at work, one corresponding to an action which is reversible up to the point of breakdown and the other to a cumulative and irreversible action. Both of these actions have been observed and explained. It is therefore clear that for any finite period of application of voltage, these cumulative effects will cause progressive deterioration until the bulk of the dielectric has become worthless as a ballast resistor, and the remainder of the insulation is carrying such a current that the critical point, where $\frac{dI}{dE} = \infty$, is reached therein, and failure occurs practically instantaneously. Thus each point on the time-voltage curve represents two actions varying in degree with the time.*

Electron Theory

Thus far, our studies of dielectric behavior have led us to explain failures in terms of volt-ampere characteristic and chemical deterioration under stress. To be consistent with the spirit of the times, explanations of these actions must be sought in the electron theory.

Considerable half-hearted groping in this direction might be recorded, involving ideas of ionization by collision or indefinite displacement or mobilization of electrons, but no really definite results have been obtained. Indeed, it is hardly reasonable to expect any more until physicists have agreed upon an atomic structure which explains the simpler phenomena of chemistry and physics. Assuming some form of molecule having a considerable number of electrons that can be detached without causing chemical disturbance, P. L. Hoover[8] suggested the following theory:

> "Both the polarization and the conductive current increase with the potential gradient, or, in other words, the number of mobile ions increases with the degree of polarization. This suggests that the mobile ions may come from the molecules of the dielectric.
>
> If this is the case there must exist for every potential gradient a state of kinetic equilibrium between the free mobile ions and the molecules of the dielectric.
>
> As the potential gradient is increased, ultimately a gradient will be reached where the number of ions required to establish equilibrium will be so great that the molecular bonds will be destroyed and dynamic rupture of the insulation will take place. In other words, at high stresses, the molecular fields will be changed and there will be a force on the electrons tending to move them in the direction of the external field. Some of the electrons will drift from molecule to molecule, and thus a conduction current will flow. The electrons that do not drift along will be acted on by the same forces, however, so that the molecules will be distorted; that is, the dielectric will be polarized. The external field thus changes the equilibrium conditions and causes a general drift of electrons."

The form of the volt-ampere characteristic, which Wagner deduced from the negative temperature coefficient of resistivity, is explained by Hoover on the basis of the above conception.

> "For low gradients the number of ions drifting, that is, the magnitude of the conduction current, will be proportional to the gradient. At higher gradients, as the polarization of the molecules increases, the molecular bonds will become weaker and the number of electrons which are drifting will increase more rapidly than the gradient, and there will be an increase in the conductivity of the dielectric. At some critical gradient the molecular bonds will be entirely broken and rupture will take place."

It must be remembered, however, that all this is purely speculative and beyond our present-day knowledge. Here, then, is an excellent field for theoretical and experimental attack.*

Another form of the same general theory is suggested by Günther-Schulze[6] as applicable to liquids. He discards the theory of ionization by collision as presented by Peek[21] on the ground that the high viscosity and low mean free path require extremely high potential gradients to produce ionizing velocities and these in turn mean localized field distortions far beyond values that are reasonable to expect. Starting from the data of Freise[36] and Koch[37] on the relation between pressure and dielectric strength, he notes the rather surprising qualitative agreement between the behavior of liquids and gases under pressure, and then suggests that slow moving ions of considerable mass leave vapor tracks in the liquid and that in these spaces, as well as in the spaces formed by occluded gases, ionization is produced by collision. He also suggests that there may be originally small vapor spaces, which serve equally well to permit higher localized velocities of sufficient value to produce ionization. In these spaces the mean free path and viscosity would be those corresponding to a vapor and not to a liquid so that the required field strength would not be excessively large. Schumann[38] presents a somewhat similar theory but calls attention to the need for obtaining further and more accurate information as to the mechanics of moving ions and other charged particles within liquids.

*This conclusion is verified by the work of Mündel[70] as analyzed by Bush and Moon.[79]

*Since the preparation of this report an important contribution on this subject has been published by Joffe, Kurchatoff, and Sinelnikoff.[80]

Research to be Undertaken

It might seem to a superficial observer that the theory of dielectric failure is fairly well established and that only a little remains to be done to round it to completion. Such, however, is far from being the case, and the remainder of this report will be devoted to consideration of some of the great mass of inconsistent experimental data which need elucidation and present a fertile field for the laboratory worker.

Breakdown Voltage and Insulation Thickness

Consider the simple problem of the variation of breakdown voltage with insulation thickness.

In the case of solid dielectrics, two facts have been fairly well known for many years, namely, that over a considerable range, the relation between breakdown voltage and wall thickness is linear, but that very thick walls are weaker than the linear relation would allow.*

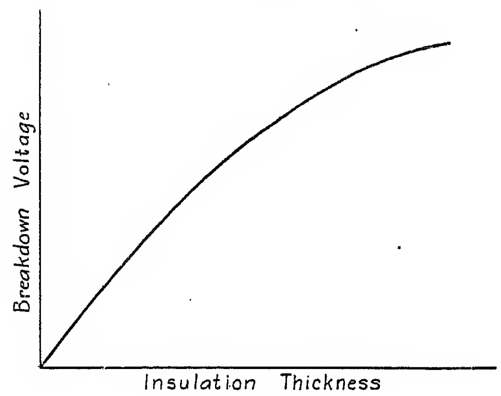

Fig. 4

This suggests a curve of the form shown in Fig. 4, which may be represented by an equation of the form

$$E = A\,T^n$$

where

E is the breakdown voltage

T is the thickness, and A and ^{n} constants.

Tests by F. M. Clark and V. M. Montsinger,[39] reported in 1925, indicate that the index depends upon the time of application of the stress, the following values being obtained for flat sheets of oil impregnated paper:

Time	Index n
Momentary	0.72
10 Days	0.56
51 Days	0.52
77 Days	0.52

This suggests an index of 0.5 for $T = \infty$.

The value of 0.72 for momentary stresses is not in agreement with most recorded data. Unpublished work by Montsinger indicates that the "momentary index" varies with the material, being unity in some cases and as low as 0.66 in others. Thus in 1912 B. S. Radcliffe,[40] working on porcelain, found a linear relation between 2 and 6 mm. This is confirmed by E. T. Montgomery.[41]

*As far back as 1902, F. J. Newbury observed that it was possible to increase the breakdown voltage of cables up to a certain point by increasing the thickness of insulation, but that beyond that point the cable would break down at almost the same voltage, irrespective of increased insulation thickness.[31]

Work in 1925, by R. Dieterle,[22] accords with the following equation:

$$E = B + A\,t$$

using the same notation as above, B being another constant. The tests, however, were on mica sheets between 0.015 and 0.30 mm. thick, a very narrow range, so that the two equations are readily reconciled as shown in Fig. 5. Moreover, the test covered periods of application from momentary to 30 min., and Dieterle agrees with Clark and Montsinger in finding that the slope $A\,B$ decreases with increasing time of application of the stress.

H. Rochow[27] worked with flint glass from 0.032 to 0.262 mm. thick and obtained a linear relation like Dieterle, except that at thicknesses from 0.15 to 0.262 mm. the breakdown voltage seems to be higher than the linear law would require. This is at variance with the generally accepted view, as expressed quantitatively by Clark and Montsinger. F. W. Peek[42] confirms the view that with alternating voltages the breakdown voltage does not increase as rapidly as the thickness, but finds the linear law to hold with direct voltages.

In the field of liquid dielectrics we find little information and that bit is not consistent within itself nor does it agree with observations based on work with solids. Peek,[21] working with transformer oil and spherical electrodes, found a minimum value for the strength when expressed in terms of the computed stress at the

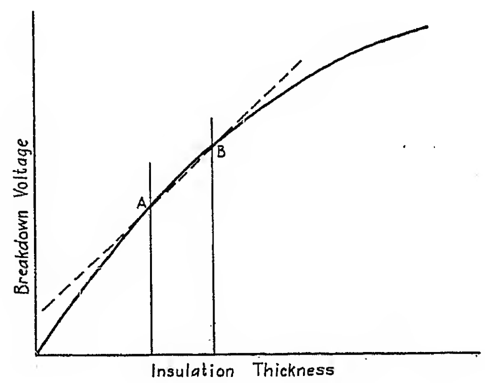

Fig. 5

surface of the sphere when the spacing was approximately five times the radius of the sphere. In terms of total volts across the gap the relations are in the form found by Dieterle although the value of the constants is different. On the other hand, his data obtained using flat disk electrodes cannot be reduced to any simple expression. In both of these cases geometrical symmetry has been ignored and it may partially explain results although Spath[43] after an extensive study, came to the conclusion that for reasonably well purified

oil the dielectric strength will increase with decrease in the separation between the electrode; with oil that is not well purified the results cannot be predicted. Wedmore[44] found that for needle points and parallel disk electrodes the total voltage was nearly independent of the gap, while Sorge found a decrease in average strength with an increase in spacing.

There is an excellent field for investigation in filling the gaps of our knowledge regarding the relation between breakdown voltage and insulation thickness, but the work must be done by trained physicists conversant with the various factors which must be controlled in order to eliminate everything but the two quantities under investigation. For instance, it is believed by some that the failure of the linear relation is due to the probability that thick material cannot be manufactured as perfectly as the thin.

The discussions which have centered about the pyroelectric theory of dielectric failure have placed much emphasis on the thickness relation. The following table shows the theoretical deductions which have been made from various aspects of the theory, Case I (b) having been developed by J. L. R. Hayden.[46]

Case	Insulation Homogeneous or Heterogeneous	Direction of escape of heat	Electrode Temperature	Relations between breakdown voltage (E) and thickness (T)	Index n in formula $E = A\,T^n$
I (a)	Homogeneous	Toward electrodes	Kept uniformly cool	Independent	0
I (b)	Homogeneous	Toward electrodes	Allowed to warm naturally	$E \ \alpha \ \sqrt{T}$	0.5
II	Weak filament along lines of stress	To surrounding insulation	(Immaterial)	$E \ \alpha \ T$	1.0

A modified form of this theory, suggested by Rogowski, which allows for changes in resistivity with voltage, as well as with temperature, gives

$$E \ \alpha \ T \text{ for thin insulation and } E \ \alpha \ \left(K_1 - \frac{K_2}{T}\right)$$

for thick insulation,[27] where K_1 and K_2 are constants independent of the thickness.

Breakdown Voltage and Insulation Area

It has been observed by many experimenters that the dielectric strength of insulating materials in thin sheet form is materially higher with small electrodes than with large ones. F. M. Farmer,[46] in 1913, found that the variation with ordinary sheet insulating materials, such as prepared paper and cloth, may be 40 or 50 per cent between electrode diameters of 1/64th in. and 8 or 10 in. The usual explanation of this phenomenon had been that the probability of a weak spot increases with the area, but Mr. Farmer pointed out that if this were the case, the probable variation should be much greater for the small than for the big electrodes* and if this were so, the difference between the maximum and minimum breakdown voltages would differ materially for the large as compared with the small electrodes. The tests, however, indicated that there is substantially the same difference, thereby discrediting the theory of probability of weak spots.

This would have been fairly conclusive had not the work of Gewerke and Krukowski,[37] in 1914, renewed interest in the probability theory These physicists made n times as many tests with small electrodes of area f as with large electrodes of area $n\,f$, took from each series of n successive tests with small areas, the lowest breakdown voltage, and found the mean of these minima to be equal to the mean of all the breakdown voltages, with large areas. This indicated that the probability of weak spots is proportional to the area regardless of whether that area is in one large unit or several small ones. These latter tests were repeated by Wagner and Stahl, who obtained the same results.[2]

The next step in this problem was taken in 1917 by A. E. Kennelly and R. J. Wiseman [illegible] who made tests with two samples of equal total area, one equipped with a pair of one-piece electrodes and the other with a large number of small electrodes. The probability of a weak spot was the same in both cases, as the total area involved was the same; nevertheless, when the small electrodes were each separately connected to the source of supply through a high resistance, the breakdown voltage was equal to that obtained with each pair of small electrodes used separately.

This seemed to point to the existence of high frequency transients, surging from part of the insulation to another, as the cause of puncture. The breaking up of the electrodes and connection through high resistance would damp out these transients whereas they would flow freely through the solid electrodes. The difference between the breakdown voltages of large and small samples would be explained by the greater severity of high frequency transients with large (high capacity) samples.†

In 1907, W. LeRoy Emmet[39] suggested that dielectric loss protects insulation from destructive voltage surges, which are absorbed and harmlessly dissipated through the mess of insulation, instead of breaking down at some comparatively weak point.

These discrepancies leave another interesting field for physicists to clarify.

Breakdown Voltage and Electrode Form and Material

Somewhat akin to the questions of electrode area are

*Because some small electrodes might cover no weak spots and others might cover one or more, whereas the large ones would be likely to cover at least one.

†Two reasons exist for supposing high frequency voltages to be especially destructive: first, the greater dielectric losses and second, the greater ionizing ability as illustrated in ozone formation.

those of their form, material, and surface. In the case of solids these details have had but little attention. There is somewhat extensive experimental work along these lines with liquids, however. In 1921 Wedmore[44] made tests to determine the best form of electrodes for testing commercial transformer oil. He came to the conclusion that the type has large influence on the uniformity of results but comparatively little influence on the average result obtained if the number of observations is sufficiently large to eliminate the experimental errors. Dieterle,[22] after using seven types of electrode, came to a similar conclusion. In 1924, Sorge[50] reported that over a considerable range the curvature radius of the electrode had but slight influence with any of several forms of liquid dielectrics. He found that the material from which the electrode was made had a noticeable effect on the majority of the values, silver being the best of eight materials tried and brass the poorest. Sorge and Engelhardt[51] both studied the influence of the condition of the electrode surface and found that it has a marked influence on uniformity of results and to some extent upon the average value obtained. Thoroughly cleaned electrodes will give smaller experimental variations and in general a higher average result. Similar observations have been reported before the American Society for Testing Materials and made the subject of a special investigation in dealing with revision of the test procedure for determining dielectric strength of transformer oil.

Breakdown Voltage and Heterogeneity of Dielectric

The relations between breakdown voltage and the degree of heterogeneity of the dielectric possibly covers the entire subject, as nothing whatever is known of the behavior of absolutely homogeneous solid insulation. The electrical continuity of such materials is almost invariably broken by minute quantities of air or moisture, and many of the most commonly used insulating materials are mixtures of substances having widely different specific capacities and resistivities.

James Clerk Maxwell showed that a dielectric composed of two substances differing in these two characteristics, will exhibit absorption phenomena which, as pointed out by F. Grunewald[52] in 1923, may have an important influence upon electric strength. Grunewald's thesis, briefly stated, is as follows:

> If a composite dielectric having two layers of different specific capacities be subjected to a condenser discharge, it will acquire different potential gradients in the two layers, the greater being in that of lower specific capacity. If now the dielectrics be discharged, the difference of potentials between the terminals will disappear, but there will be an internal potential gradient due to charges at the surface of separation.
>
> After an interval, this internal potential curve will straighten and establish a potential difference between electrodes, and the gradient in each layer will now be proportional to its conductivity instead of inversely as its specific capacity.
>
> If, now, a new condenser discharge occurs of such polarity that it will add its potential to that due to the residual charge, a severe stressing of the low capacity layer will result, especially if that layer has the higher resistivity.

This view was supported by experiments which showed a marked decrease of puncture voltage as the result of precharging.

Attempts by other physicists to duplicate these experiments have led to inconclusive results.

The presence of occluded air is a serious detriment to solid insulation, as shown by J. B. Shanklin and J. J. Matson[53] in 1919, as it leads to excessive local dielectric losses and to destructive chemical action under powerful electrical stresses. In the same year, F. Dubsky[54], reported experimental work on the electric strength of thin films of air and showed that the ionization stress is considerably higher than in thick films.

The stress in an air film is K times that in the contiguous solid dielectric, where k is the specific capacity of the latter. Hence knowing k and Dubsky's experimental data, it is possible to predicate the stress in the solid dielectric at which air ionization begins. Shanklin and Matson found this to be 19 kv. per cm. in the case of impregnated paper cable insulation. The detrimental effects of such ionization were described by J. B. Whitehead[55] in 1923.

It was shown in 1922 by Del Mar and Hanson[56] that impregnated paper insulation acts as oil insulation reinforced by baffles. When, however, the oil has been altered chemically as the result of exposure to ionized oxygen, the oil hardens and the insulation degenerates to a laminated type with air or vacuous spaces between layers.

By their nature, fluids lend themselves better than solids to studies of the effects of impurity and the literature contains reports of many such studies. Hendricks [15,57] in 1910 was among the first to report on the effect of moisture on the dielectric strength of transformer oil. He succeeded in deriving results which he reduced to the form of an equation covering small limits. Freise[36] made extensive studies and found that the amount of moisture was only one factor; the extent of diffusion was almost equally important. Hayden and Eddy[58] report the result of 3000 tests of the dielectric strength of transformer oil. They came to the conclusion that one of the principal factors influencing the uniformity of results is that of moisture. In their tests they used commercially dried oils. Schroter[59] arranged a test electrode so that the process of dielectric failure might be observed under a microscope and was able to establish clearly that breakdown was preceded by the movement of minute dust particles into the space between the electrodes. He found marked improvement in the dielectric strength of the oil as the

moisture and dust were removed by successively more refined methods of treatment. Spath and Wedmore both report more irregular results with moist oil than with dry. Gyemant[60] has developed a mathematical theory to explain dielectric failure of liquids where moisture is present in small globules as the diffuse phase. This treatment is interesting but does not seem to have any great practical application.

Breakdown Voltage and Temperature

If the failure of insulation is due to the heating resulting from dielectric energy loss, the breakdown voltage should drop with rising temperature, and failure should be preceded by temperature rise.

As with most experimental data relating to the failure of insulation, the facts are apparently inconsistent. Thus G. Weimer and C. T. Dun[61], experimenting with porcelain, reported a progressive drop of momentary electric strength from 25 deg. cent. to 325 deg. cent. at which latter temperature this material possessed no electric strength whatever. Similarly, W. S. Flight[62] stated in 1922 that composite materials like varnished cambric, mica products, impregnated paper, etc., all suffer a marked decrease in dielectric strength, ranging from 5 per cent to 72 per cent for a rise from 30 deg. cent. to 100 deg. cent., the voltage being increased by steps of one-minute duration.

Opposed to these results are the more recent and carefully obtained data published by H. Rochow[27] in 1925. This physicist used double concave specimens of Jena flint glass and made his tests over a range of 108 deg. cent., namely from 18 deg. to + 90 deg. The minimum thickness of insulation was 0.175 mm. and the rate of increase of voltage 340 volts per sec. The net result was a practically uniform electric strength over the whole range of temperatures.

Furthermore, Rochow found by an optical method based upon the change of refractive index with temperature, that no temperature rise, exceeding 10 deg. cent., occurred even when a voltage near the breakdown point was applied for 10 min. or longer until failure occurred. It was pointed out by Rogowski[28] in 1924, however, that according to Wagner's filament theory, a temperature rise of 5 deg. cent. should be sufficient to start accumulative heating in glass, so that Rochow's results are inconclusive. Here again is a field for investigation which has important aspects both from the practical and scientific points of view.

Results obtained with liquids in an effort to determine the influence of temperature are too varied to leave us with any idea as to their true significance. Sorge[50] found that xylol was almost uninfluenced by temperature between 20 and 80 deg. cent. while above 80 deg. there is a slight dropping off in dielectric strength. Hexane showed steadily decreasing values and an abrupt falling off after the temperature had risen above 69 deg. cent. Still another form of relation was obtained with transformer oil which showed slightly increasing values up to 50 deg. cent. and beyond this point a slight decrease.

Breakdown Voltage and Rate of Variation

It is difficult to distinguish experimentally between the effects of voltage and time as discussed under the heading, Time—Voltage Relations, and those having to do with effects of the rate of variation of voltage, for where the time of test is comparatively short the two influences tend to mask one another.

It has long been known that with solid dielectrics the electric strength increases with increasing rates of application of the voltage. This is clearly illustrated by the following data submitted by H. Rochow[27], a result of careful tests on Jena flint glass 0.167 cm. thick:

Volts per sec.	Kv. per cm.
26	2900
340	3810
650	4310

R. Dieterle,[22] experimenting with mica sheets from 0.015 to 0.030 mm. thick, and over a range of frequencies from 0 to 50,000 cycles, found the breakdown voltage both for momentary and 30-sec. applications, to be practically constant from 500 to 50,000 cycles. The average for all thicknesses was as follows, taking for both momentary and 30-min. periods a base of unity for 50,000 cycles:

	Relative Electric Strength	
Cycles	Momentary	30 Minutes
0 (d-c)	15.6	5.53
0.5	2.42	1.59
10	1.29	1.15
50	1.22	1.15
500	1.16	1.10
5000	1.12	1.09
50000	1.00	1.00

In general, it would appear that a dielectric will withstand a higher voltage if applied rapidly than if applied slowly.

As far back as 1908, A. S. Langsdorf[63] reported that at frequencies from 30 to 110 cycles, breakdown occurs after a definite number of repetitions of the electric stress, provided the applied voltage is above a certain critical value. It is interesting to note that this is consistent with the findings of F. M. Clark, regarding accumulative injury with intermittent voltage of long duration.[65]

Work by F. J. Vogel,[64] in 1924, on oil impregnated fullerboard, over a range of from 60 to 400 cycles, confirms Langsdorf in a general way, but indicates that the law of cumulative injury does not represent the facts with precision for such frequencies. Secondary actions are likely to complicate the results, especially if air is present, as ozone generation is almost proportional to the frequency.[65]

If these effects which are so prominent in solids are

present in true liquids, the values seem to be so small in general as to have escaped detection. However, Dieterle[22] reports that with semi-fluid oils, he found a noticeable difference between the dielectric strength when the voltage was increased step by step in amounts of two-kv. each minute and that obtained when the increase of voltage was uniform and rapid so as to obtain failure in a few minutes. If the rate of application of voltage is increased to very high values, new phenomena are introduced. Peek[16] has investigated the behavior of commercial transformer oil when subjected to rapidly applied impulse potentials and finds that the dielectric strength under these conditions may be as much as four times that obtained with rapidly applied 60-cycle potentials. These tests indicate a clear time-lag although it is somewhat larger than that obtained for air and rather smaller than that obtained for solids under approximately similar conditions.

Comparison of Direct and Alternating Potentials

It has long been known that insulation will stand a much higher direct than alternating voltage. Thus, F. W. Peek,[42] in 1916, showed that the "d-c. breakdown voltages" of solid dielectrics in good condition are generally higher than the alternating crest voltages, especially when the time of application is long and the insulation thick. When appreciable amounts of moisture are present, the direct and alternating crest voltages are approximately the same.

J. Delon, W. S. Clark, and others have determined the ratio of direct to alternating voltages for oil impregnated paper, and in 1923, J. L. R. Hayden and W. H. Eddy[66] published a very comprehensive report on the subject. They showed that the ratio of direct to alternating 60-cycle crest voltage varies with temperature, insulation thickness, and rate of application of voltage.

The following figures for oil impregnated paper are typical:

Temperature 6 deg.	25	50	75	100
Ratio	2.04	1.64	1.61	1.53

Thickness, number of layers	2	4
Ratio	1.86	1.65

Rate of voltage rise, per cent per second	20	5	0.1
Ratio	1.86	1.58	1.78

There is abundant opportunity for research work in analyzing the changes of ratio and amplifying the scope generally, especially with relation to the time element.

It is well recognized that for air, the value of the direct potential and the crest value of the a-c. potential to produce failure are the same. We are not surprised, therefore, to find that investigations on liquids indicate a ratio of more nearly 1.00 or about the same value as for gases. However, it is a little surprising to find that Hayden and Eddy[58] report that for a Number Six Transil oil they obtained an average ratio of 0.975 for a two-mm. gap and 0.871 for four-mm. gaps and only slightly higher values, namely, 0.965 and 0.969 at two mm. and four mm. respectively. Using petrolatum, Sorge[50] reports what seems to be a more probable value as a result of tests on hexane when he gives 1.095 as the ratio between the direct potential and the crest value of the corresponding 60-cycle alternating potential. Using the same material and the same arrangement of test electrodes, the 50-cycle value was 1.36 times the d-c. value to produce failure, the time of breakdown being essentially constant and only a few minutes in either case. Draeger found similar results, but differences in test electrode and other details of procedure make it difficult to compare absolute values. He also reports that when alternating potentials are used, the "root-mean-square value" is of importance, as well as the crest value; the lower the r. m. s. value, the higher the crest value to cause breakdown. This is quite in line with results previously referred to in connection with the effects of impulse voltages on transformer oils.

Breakdown Voltage and Pressure

In 1902, Perrine[78] noted the effect of rarefied gases in lowering the dielectric strength of insulation. Koch[37] reported in 1915 the results of elaborate tests on some fluid and semi-fluid insulating materials with the somewhat surprising conclusion that for pressures up to 20 atmospheres the breakdown strength may be expressed by the following formula in which p is the pressure in atmospheres:

$$\text{Breakdown strength } (\text{Kv.}_{eff}/\text{cm.}) = a + b \cdot p$$

But there is a definite limiting maximum value for each liquid above which the dielectric strength is approximately constant. The factor a has values between 75 and 100 while b ranges from 5.0 to 13.0 and depends on the material. In some cases the limiting pressure was found to be as high as 50 atmospheres.

While this study was made the basis of the theoretical work of Gunther-Schulze previously referred to, very little significance seems to have attached to it until recently, although H. W. Fisher and R. W. Atkinson[67] obtained a patent in 1925, based upon a dielectric composed of a combination of compressed air and a solid. These investigators stated that pressure increases, in marked degree, the dielectric strength of insulation containing occluded air bubbles by reduction of internal corona effect.

L. Emanueli, about the same time, developed a special high-voltage cable in which provision was made for expansion and contraction of the oil. He also showed the effect of variation of air pressure upon dielectric losses.[68] In 1926, W. A. Del Mar[69] called attention to the consequences of the creation of voids by thermal contraction of oil in impregnated paper, pointing out that ionization will occur in ordinary high-tension cables unless the internal pressure is maintained above atmospheric.

Isolated Phenomena

A number of very curious phenomena has been noted which probably bear upon the ionization or electron theories. For instance, if a solid dielectric in series with air be subjected to an increasing alternating stress, at first a small positive charge is induced on the surface of the solid dielectric which, with higher stress, changes to an increasing negative charge until puncture takes place.[71]

Work on air suggests that the disruption of a dielectric may be principally the work of positive ions, the negative ions being of secondary importance. Perhaps this phenomenon is related to the preceding one.[72] Very high gas pressure can be created by an electric spark in a confined area, as shown by K. B. McEachron[73] in 1923, which may lead to the mechanical disruption of a solid dielectric in which sparking occurs due to air fissures.

If the duration of the applied voltage is short (say, 10^{-6} sec.), water disrupts like a dielectric and has several times the dielectric strength of air.[74] This suggests that pure water may be a dielectric differing from others, principally in its time-voltage function, the time required to produce ionization being very short, failure by conduction occurring if the time be any longer.

There is some evidence that ionization initiated by an over-voltage may persist at a lower voltage.

It was pointed out by W. Petersen that small funnel-shaped craters are likely to form in insulation from which ions may be shot into the surrounding medium.[75] Nelson Goodwin,[76] in 1925, told of an interesting experiment which suggests the ionic bombardment of Petersen:

> A plate of glass was tested, large enough to spark around at about 50,000 volts but which could not be punctured. A small patch of paraffin wax was then melted on the glass and allowed to cool. One of the electrodes, consisting of a wire 0.040 in. in diameter, was allowed to rest on top of the paraffin, end on. The other electrode under the glass was a disk about 1 in. in diameter. Under these conditions a potential of less than 30,000 volts was required to puncture glass and paraffin together. The absence of spark noise was very noticeable during the paraffin test in comparison to that when glass was tested alone.

The lowering in breakdown voltage might be accounted for by the introduction of ions sufficiently mobile to be accelerated to a velocity which will cause break-up of the glass molecules, or on the other hand by the stress concentration due to the specific capacity of the oil.

The test is an important one and the matter needs further investigation. The experiment has since been repeated successfully by others, using glass from photographic plates and drops of petrolatum, paraffin, and other oils. Water on glass, or oil on varnished cambric has no such action.

Perhaps connected with this is the remarkable increase of electric strength of oil when the electrodes have been very carefully cleaned. This has been previously mentioned under the heading, Dielectric Strength and Effects of Electrode Form and Material. When the electrodes are cleaned by washing off with carbon tetrachloride or benzol and are dried by passing them through the flame of a burner with a draft of warm dry air, the results are invariably much higher and more uniform than when the same oil is tested with electrodes prepared in the methods used for commercial testing.[77] In this latter method it is customary only to wipe the electrode and rinse out the test cup with a sample of oil free dry gasoline in order to remove fibers. However, there is another possible explanation than the one suggested and it has to do with the complete removal of small fibers such as would be accomplished by the action of the flame. Some work bearing on this phenomenon has been done, using x-rays and radium emanations on the dielectric but the results have generally been too indefinite to prevent forming the basis for any thorough-going theory or explanation.

Another peculiar condition was noted by Przibram in 1904 and quoted by Gunther-Schulze[6] after working with organic liquids. In general, it may be stated that first, in a homologous series the dielectric strength decreases with increasing molecular weights; second, the introduction of a halogen atom or the NH_2 group causes in benzol a considerable increase in dielectric strength; and third, oxygen-compounds seem to have a greater dielectric strength than the corresponding hydrocarbons.

These phenomena differ from those previously recorded in that they have not been correlated with other phenomena or theories.

Conclusion

Viewing the subject as a whole, while far from being on a satisfactory footing, either from the practical or theoretical standpoint, the developments of the last three years have given us a rough survey of the field with sufficient bench marks to enable us to visualize the general character of the intervening territory and to project our vision some distance beyond.

Research work can now be undertaken with an understanding of its significance in the general scheme of things, so that experimental work can generally be counted upon to have a broad as well as a specific significance.

This is a great advance over the empiricism of preceding years with its fragmentary and undigested data and crude theories.

Summarizing this report as a starting point for future research work, we may state our present position with regard to solid and liquid dielectrics as follows:

1. Dielectric failure is a phenomenon of circuit instability,

2. This instability results primarily from the form of the stress-current density curve, which has either an infinite or a negative slope in its upper ranges,

3. The explanation of this unstable characteristic is possibly to be found in the equilibrium conditions of free and combined electrons or other ions. In many cases these ions may be due to the presence of impurities in what we ordinarily consider to be the basic material,

4. A dielectric is not necessarily injured by operation at stresses corresponding to instability unless the entire circuit has unstable characteristics; hence this action is non-cumulative and reversible,

5. A dielectric under stress is subject to deterioration due to the energy of electric fields being destructively absorbed, in affecting chemical changes directly or by generating heat. This action is generally cumulative and irreversible,

6. In solids, practically every known instance of cumulative and irreversible deterioration seems to be traceable to the presence of gases or liquids although it is conceivable that this phenomenon might even occur in a pure solid dielectric. In the case of liquids, it does not seem to be entirely dependent upon the presence of impurities for there is considerable evidence of chemical changes of various types where hydrocarbons and similar liquids are used. No evidence is available as to the performance of liquids of simple molecular structure and consisting of one chemical element only, so that change is impossible,

7. The form of the time-dielectric strength curve is explained by both the reversible and the irreversible actions being at play, the former predominating for a short period and the latter for a long period,

8. There are indications that the cumulative deterioration in solids resulting from heat generated in the dielectric may be serious even for periods of less than a second in duration. In liquids no evidence of any kind having bearing on this point has been presented,

9. Attempts to frame a quantitative theory of dielectric failure in solids on the basis of heat generation and the negative temperature coefficient of resistivity which is characteristic of these dielectrics have not given quantitatively correct results,

10. The pyroelectric theory is not basically unsound but it will not be useful until it has been made part of a more general theory which must take many more factors into account,

11. The only theory approaching to general application to explain dielectric failure of liquids assumes the presence of gaseous or vapor spaces within the liquids so as to permit the development of velocities sufficient to cause ionization by collision and the consequent production of additional ions as evidenced by increase in current,

12. A theory to explain the failure of dielectric liquids due to the presence of moisture has only limited application and cannot receive a serious place in this report,

13. Future progress is dependent largely on obtaining reliable data by carefully controlled experiments on a wide range of materials and carefully noting the influence of gaseous, liquid, and solid impurities. These experiments should establish the relations between dielectric strength, thickness of dielectric, area of dielectric or form of electrodes, material of electrode, form of the voltage current waves, temperatures of dielectric and electrodes, mechanical pressure, and other variable factors,

14. Various isolated phenomena should be carefully studied. These are likely to prove more valuable leads than phenomena that are better understood.

Discussion

F. M. Clark: I think if you read this paper carefully you will come to the conclusion that there is a considerable difference of opinion among "reliable experimenters." That is due, no doubt, to a fact which heretofore has been greatly ignored. Not until recently have the chemist and physicist come into agreement with regard to the structure of the atom. The chemist has had his own chemical atom, and the physicist his own physical atom. The real reason has been that the physicist has entirely neglected the chemist's problems and the chemist has been guilty of neglecting the problems confronting the physicist.

The chemist is compelled to recognize two entirely different types of material; that is, the organic and the inorganic. The molecular structure involved appears to be different for each of these classes.

The electrical engineer, however, disregards both the chemist and the physicist; he works upon "insulation" and pays no attention as to whether it is organic or inorganic material. I think if you go through the paper and pick out the discrepancies, you will find one man talking about inorganic matter,—glass or the like,—and the other man talking about oiled paper or other organic material.

Another point I want to bring out in the paper is the difficulty in handling empirical equations. For example, take the case of the time-voltage curve, described on the third and fourth pages. Mr. Del Mar points out that the index of the time factor obtained by Peek and Montsinger is -4. Mr. Farmer indicates that it ought to be -7 instead of -4. Now, we have found that you can change that index as you please, by merely changing the materials with which you are impregnating the paper, or using the same impregnating material and changing the solid. In using an empirical formula, therefore, one must be very careful to apply it only to those limited cases for which it has been already proved.

Mr. Del Mar asserts that the dielectric strength-thickness relation for oil-impregnated paper is 0.72. It ought to be stated as 0.72 for mineral-oil-impregnated linen paper. If you go to Kraft paper, it is something else. As a matter of fact, we have been able to change the strength-thickness relation at will merely by changing the type of material with which we are dealing. We have gone from a value of 1 to an index point of about 0.58, either by changing the solid or the oil. That is brought out in a paper to which Mr. Del Mar refers as unpublished. It was published by Mr. Montsinger and myself in the *General Electric Review* in 1925.

There is one other point. It is mentioned that there are two classes of breakdown. I should like to add another. The mechanical effects leading to electrical breakdown have been entirely neglected, except at the bottom of the column. I think they are extremely important, especially to the cable engineer and operator.

I can cite a case. In 1923 at Pittsfield in some of our apparatus which had seen field service, we found considerable wax formation. The problem of the cause of this wax formation

was turned over to our laboratory. The chemists attacked the work, and in a short space of time came to rather definite conclusions regarding its origin,—conclusions which have been quite widely accepted since that time. They claimed the wax was nothing but a polymerizing product produced by the action of corona on the oil. They concluded that the corona was first, the wax being the result and not the cause. Nevertheless, we continued the work to determine the possible advantage occurring from the use of an oil which would not wax easily under corona bombardment. We found that if we took oil which did not wax easily, or if we used air impregnated paper, and subjected either of them to corona, we got a mechanical shock and the paper disappeared. They told us it was the oxidizing action of ozone on the paper. However, we could not find carbon dioxide after or during the experiment. We repeated the experiment in a hydrogen atmosphere. If we stopped the experiments halfway, "needle points" were noted, such as Osborn described some time ago. Eventually, with a continued test, the paper lost its structure and disappeared as a powder.

Can an oil be produced which will not wax under corona bombardment? This problem may not yet have been solved to the satisfaction of all. Perhaps such an oil may be eventually found, although its existence does not appear probable at present. However, suppose such an oil can be prepared, what will be the result? We shall then have to consult the paper chemist in order to obtain a paper which will not disintegrate under corona. In the end, we may reach the surprising viewpoint that wax formation in cables is not our worst enemy after all. It at least gives us a true indication of the condition of the cable before failure. I believe wax formation in cables will be well worth the trouble it has caused if it serves to focus attention on the fact that, to insure proper service, the cable must be not only properly treated at the factory but throughout its entire existence before and after installation must be handled in such a way as to prevent the formation of voids, gas pockets, and "dry" spots.

W. A. Del Mar: Mr. Clark's discussion clearly shows the necessity of attacking the insulation problem in a broad comprehensive way and of avoiding hasty generalizations. Since the preparation of our report, several papers on dielectric failure have appeared which, we are glad to note, support the main conclusions which we reached from the rather meager data previously available, such as the existence of two agencies of deterioration, neither of which is explained by the Wagner theory in its present forms, although a modified form of this theory may be expected to explain one of them.

W. F. Davidson: I think that we can only again emphasize the points which Mr. Clark has brought out; the need for clearly understanding that about which we are talking, and following the thing through with attention to every minute detail. So many times after the work is all done we find some essential point that might easily have been secured during the progress of the work still lacking. Somebody starts out to study the pyroelectric theory of material, and when he gets through, he finds that the thing has acted in a disruptive way, and that evidence bearing on the disruptive failure is quite useless because it has been collected in such a haphazard way.

Mercury Arc Rectifier Phenomena

BY D. PRINCE[1]

Fellow, A. I. E. E.

Synopsis.—*Peter Cooper Hewitt invented the mercury arc rectifier in 1902, so that it can hardly be considered a new development. More than a half dozen different manufacturers are producing mercury arc rectifiers of various types and sizes and have been producing such rectifiers for years, so that commercial development is not new, yet technical literature is astonishingly bare of treatments going to the fundamentals of rectifier behavior. Many articles appear, describing this and that installation. Descriptions of structural details are not wanting. For specific glass rectifiers, performance curves are available which give the relation between current and voltage at which failures occur under standard conditions. Even this information does not seem to be published for the iron tank rectifiers.*

An engineer wishing to familiarize himself with the quantitative relations underlying rectifier design has thus practically nothing to go on. We cannot assume from this that manufacturers the world over have proceeded blindly for nearly a quarter of a century, but if they do know what happens in a mercury arc rectifier they at least have not told the public.

The purpose of this paper is to present such information as is at present available to the author. This information does not include the knowledge of very important groups in the industry and would even seem to indicate that a very large aggregate capacity of rectifiers has been designed along incorrect lines. This offering is then made in a spirit of humility in the hope that those who know will point out wherein it is in error.

INTRODUCTION

FOR the purposes of this paper, structural details will be ignored as far as possible. That is, if a vacuum-tight vessel is secured, the performance of a rectifier of a given size and shape should not be altered whether the joints are sealed with mercury or rubber, or are of glass fused to metal. Erratic behavior due to bridging of insulators with mercury or oxidation residues merely hampers an investigation and is not a factor in fundamental design constants. Similarly, disturbances due to flying drops of mercury must be prevented, but this again should not be determining where size and shape are to be fitted to current and voltage ratings.

The function of a rectifier, as every one knows, is to convert alternating into direct current. This it does by an electrical action analogous to the familiar check valves used in pumps. A mercury arc rectifier consists of an evacuated vessel of glass or metal containing a mercury pool cathode and two or more anodes. A bright dancing spot on the mercury surface is the source of electrons which move toward any positively charged anodes. As long as the anodes are unable to give off electrons, conductivity in the other direction is normally nil. These phenomena are developed more in detail in subsequent sections.

THE CATHODE SPOT

The probable mechanism of the cathode spot is substantially as follows: Electrons are emitted from the spot and proceed into the space where they strike neutral vapor molecules and ionize them by removing an electron. The new electron joins the old in conducting the current. The remainder of the molecule has a net positive charge and is a positive ion. It is attracted to the cathode. As the positive ions approach the cathode, they produce a high space charge potential gradient which removes electrons from the relatively cold mercury surface. At the same time, the positive ions striking the surface heat it and cause a violent evolution of mercury vapor. As the ions are also mercury vapor, a pressure of mercury vapor is built up which enables the electrons to strike molecules after a very short travel. The entire process can thus take place very close to the mercury surface which enables a very few volts to produce a gradient of millions of volts per centimeter at the surface.

The cathode spot has been observed to have an area of 2.5×10^{-4} cm.²/A. It moves about at a rate of 10 meters per sec. due to the vapor blast. It is relatively cool, not over 600 deg. cent. This point is demonstrated by noting its spectrum which is of the band type rather than the continuous spectrum radiated by a hot body. The vapor pressure is about 2.58 atmospheres, 1.8 atmospheres due to arriving positive ions and 0.78 to evaporating mercury. This pressure gives a mean free path of the order of 3.76×10^{-6} cm. near the surface. The cathode drop is about nine volts so that the average gradient over one mean free path is about 2.5 million volts per cm. The removal of the electrons from a cold metal surface by high gradient is called the Schottky effect. Schottky calculated on theoretical grounds that about 40×10^{6} volts per cm. would be required for perfectly plane surfaces. For curvature of the order of molecular dimensions the average gradient might be reduced a great deal so that 2.5×10^{6} would seem a reasonable value. Excepting the spot temperature, most of the foregoing figures are due to Guntherschulze[2] who gives also a division of the lost energy. Mercury evaporated is 7.2 × 10 [illegible] g. per sec. per ampere. Fifty-six per cent of the current at the cathode is carried by electrons, the rest by ions moving toward the cathode surface. At greater distances, almost all the current is carried by electrons on account of

1. Research Laboratory, General Electric Co., Schenectady, N. Y.

2. *Engineering Progress*, August, 1925; *Zeit für Physik* Band 11 Heft 2, 1922.

the slow movement of the heavy ions. An electron has a mass of 9×10^{-28} g. and carries a charge of 1.59×10^{-19} coulombs, while an ion carrying the same charge has a mass of 3.3×10^{-22} g. Their velocities are inversely proportional to the square roots of their masses, so that the electron velocity is about 600 times that of the mercury ion in the same field.

The ionization potential of mercury vapor is 10.4 volts; however, all this energy need not be imparted at one collision. A molecule may be activated by receiving 4.7 volts in which condition its free electrons are in an outer position from which they are more easily detached. The nine-volt cathode drop is presumably a weighted average of the various possibilities. 0.44 ampere, the positive portion of each cathode ampere, falling through nine volts, delivers 3.96 watts to the cathode. On entering the mercury, the ions are neutralized by conbination with electrons, and this releases further energy equal to 3.1 watts. The total energy is thus 7.06 watts per ampere. This energy is consumed as follows:

Consumption of energy by electrons leaving the mercury	2.20 watts
Evaporation of mercury in the cathode spot	2.20 watts
Conducted away by the mercury	2.68 watts
	7.08 watts

The heat conducted away by the mercury may evaporate mercury outside of the cathode spot or may be conducted to the outside of the rectifier. The electrons passing out through the nine-volt cathode drop acquire energy represented by $0.56 \times 9 = 5.04$ watts which is used in making ionizing collisions, but 3.1 watts is returned to the mercury by the positive ions. The difference, 1.94 watts, passes into the ionized space but must be added to the 7.08 to make up the total cathode drop. $7.08 + 1.94 = 9.02$ volts.

Conduction in Space

Once free of the cathode, the gas expands to a low pressure, which will be considered later. In this space the electrons travel in the general direction of the anodes but they are diverted by collisions with vapor not violent enough to ionize, and this adds heat to the vapor. Some electrons recombine with ions, giving off energy as radiation which is lost. Electrons and ions combine on the surface of the vessel giving up their energy as heat. These losses must be made up by a potential drop along the arc path. Data have been published giving this loss as 0.1 to 0.4 volts per cm. of arc length. It is thus quite variable and depends upon a variety of factors, such as temperature and geometry of the rectifier. In any given volume of ionized vapor there will tend to be equal numbers of electrons and ions at any instant. A surplus of either sign of charge will attract charges of the opposite sign until the balance is restored. Since for equal energy the electrons move 600 times as fast, the conducted or drift current will be carried by electrons and positive ions in the ratio of about 600 to one. The walls of the rectifier, if at space potential, would receive 600 times as many electrons as ions. They could therefore remain at space potential only if a large current were drawn from them. Actually the walls are usually allowed to charge themselves negatively until a balance is reached. This balance occurs when the walls are negative about five volts with respect to the space potential or about four volts positive with respect to the cathode. The cathode drop was thus long supposed to be the difference between the wall or sounding electrode potential and the cathode[3].

Anodes

The deflection of electrons and ions from the straight path by collisions gives rise to random velocities which may considerably exceed the velocity of drift toward the anode. Langmuir[3] has found that the density of electrons striking a test electrode is from 1½ to 4 times the drift current through the rectifier, depending upon the temperature. It is thus possible for an anode to collect all its current merely by picking up electrons which naturally strike it. These electrons give up their energy upon falling into the anode surface so that the anode is heated even though there is, strictly speaking, no anode drop.

Theoretically, a large enough anode might collect its entire current while at a potential negative with respect to the space. A metal tank rectifier employing the whole tank as an anode will show a drop as low as eight volts for considerable currents. The total drop is thus less than the cathode drop alone. Such an arrangement would be more or less impracticable for an operating rectifier but serves to show the nature of the anode loss.

Most practical rectifiers are arranged to have enough anode area so that the entire current is random current at ordinary loads and working temperatures. This is accomplished by making the anode area not less than ⅔ of the cross section of the arm in which it is located. The anode is then required to dissipate only the energy of recombination of the electrons; that is, the work function which is 3.7 volts for iron and 4.1 for graphite. This energy may be conducted away in anodes with cooled stems or radiated where small solid stems are employed.

If, due to insufficient anode area or a cold tank, the random current is too low, the anode must surround itself with an electric field to draw additional electrons in. This field accelerates the electrons which reach the anode at high velocity and cause excessive heating. It is not uncommon for the anodes in a cold tank suddenly loaded to become incandescent or melt, giving a failure before the apparatus has time to warm up.

3. Langmuir, *G. E. Review*, Nov., 1923, and July, Aug., Sept., Nov., and Dec., 1924.

Total Arc-Drop

The total arc-drop from anode to cathode of a rectifier is easily investigated. Fig. 1* gives the arc-drop of a small glass tube under various conditions. The lower curves are taken with a tube having short straight anode arms. With natural air cooling, direct current was first collected by one anode and then by two in parallel using a resistance to divide the current. The curves are the same within the limits of experimental error. Also it is impossible to make two anodes divide current without some external means, for even though the drop increases with slow increase of current, it seems to drop with instantaneous increases.

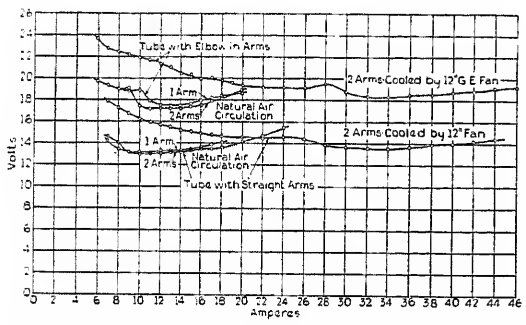

Fig. 1—Arc-Drop for 20-Ampere Glass Tube

The upper curves are for a precisely similar tube with bent anode arms which are necessarily longer. The point of minimum drop is perhaps the best to take for comparison between different sizes. Table I gives an idea of the erratic connection between length of arc and total drop.

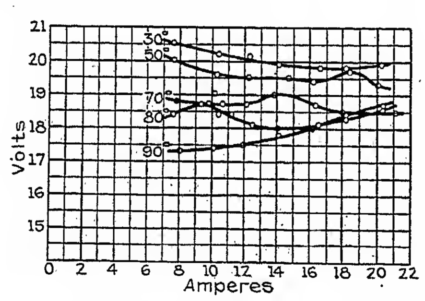

Fig. 2—Effect of Temperature on Arc-Drop of 20-Ampere Glass Tube

TABLE I

Minimum Arc-Drop for Various Rectifiers

Glass	Size	Minimum drop
	10 ampere	16
	20 "	17.1
	30 "	15
	50 "	15
	250 "	17.2
Steel	15 inch	14.1
	30 "	14.8

*Figs. 1, 3, 11, 12, 13, 14, 16, 18, 19, 20 are reproduced from "Mercury Arc Rectifiers and Their Circuits," by Prince and Vogdes, through the courtesy of the McGraw Hill Book Co.

Fig. 1 also shows the effect of fan cooling the same two tubes. The point of minimum drop is moved to a considerably higher current but the minimum drop itself is larger. The temperature effect is clearly shown in Fig. 2. For small currents the drop is much lower at high temperatures.

The drop as a function of time is shown in Fig. 3. A rectifier was operated under oil at carefully controlled temperature and a record made of current and arc-drop. The arc-drop measurements at the same temperatures and currents obtained from d-c. measurements are shown dotted and check quite closely except at the transfer points where two anodes were exchanging current.

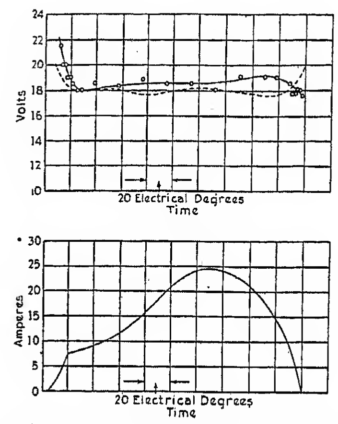

Fig. 3—Instantaneous Arc-Drop Variations

The effect of fan cooling in Fig. 1 suggests that even more current could be carried by more intensive cooling. Fig. 4 shows the effect of additional cooling on the same tube. Additional current possible with water cooling is accompanied by a considerable rise in arc drop. The connection between the increased minimum and tube shape is shown by comparing Fig. 4 with Fig. 5. The two tubes have almost the same external area but the one of larger cross section not only carries more current with natural cooling but allows an almost indefinite increase in current without much increase in drop under forced cooling. The sudden changes in drop attract attention, but we are not

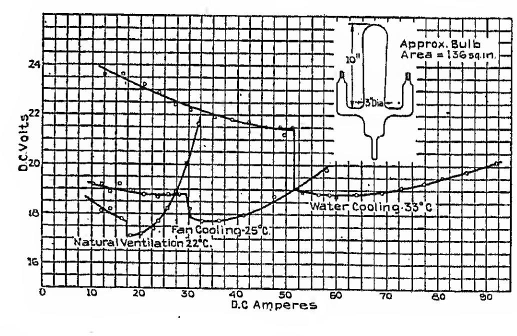

Fig. 4—Effect of Cooling on Arc-Drop of 20-Ampere Glass Tube

prepared to offer an explanation for them. It is associated with the anode conditions. When the drop is high, the whole anode is covered with glow. When it is low, the anode tip appears to receive most of the current.

When the vacuum is extremely poor, excessive arc-drops are obtained. The additional drop appears to be

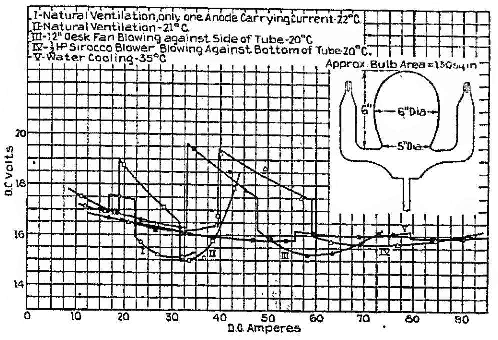

Fig. 5—Arc-Drop in Glass Tube of Large Cross Section

in the arc stream which contracts and becomes very hot, even melting glass or iron where it comes in contact at turns in the passage. The anode is also likely to be heated locally. A voltage breakdown or arc-back, however, will usually occur in operation long before this state is reached.

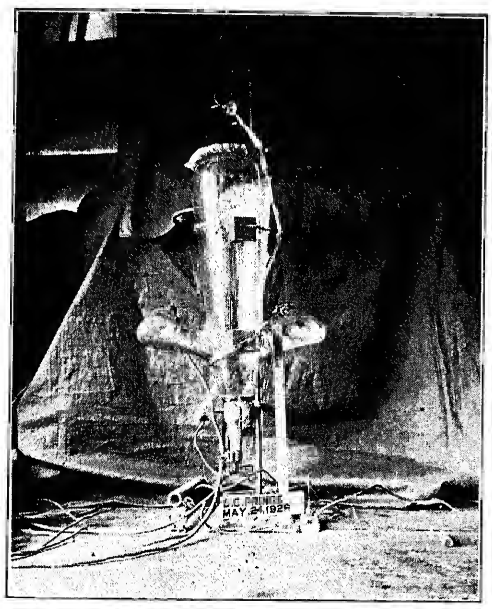

Fig. 6—50-Ampere Tube Arranged for Vapor Pressure Measurements

Pressure Measurements

It seems as though there should be some connection between arc drop and the pressure in the vessel. Certain difficulties interfere with direct measurements of these pressures. A gage connected to the outside will measure the pressure of fixed gasses plus some mercury vapor pressure. If a MacLeod gage is used, the mercury vapor will practically all condense under compression. If the hot wire type of gage is used, connected by a small tube, the mercury may not all be condensed, but an indeterminate part will be condensed so that the reading is of doubtful value as far as indicating the total pressure in active zones in the rectifier. The hot wire gage cannot be introduced into the arc stream because recombination will then take place on its surface and the heat of recombination may more than offset the convection due to the gas on which the pressure indication depends. Similar difficulties prevent reliable measurements of temperature inside a rectifier. Investigators have thus been more or less in the dark as to the actual conditions in the arc stream and condensing chamber.

At the suggestion of Dr. Langmuir, a new method has been worked out for measuring pressures and temperatures within a mercury arc rectifier. Small copper

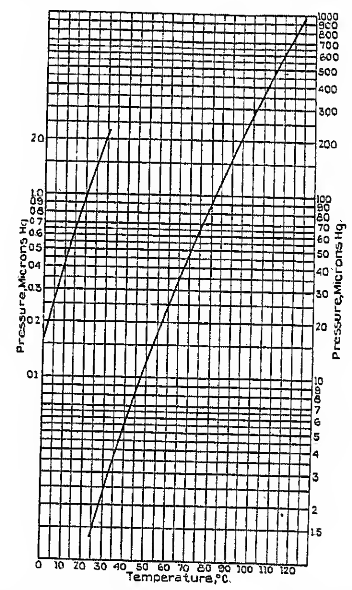

Fig. 7—Temperature and Pressure of Saturated Mercury Vapor

thermometer wells are attached to the sides of a rectifier, as shown in Fig. 6. By heating and cooling these wells, the temperature is found at which the mercury just condenses or just evaporates from the inside surface. These temperatures are within one or two degrees of each other. At the balance temperature, the amount of mercury condensing must be equal to the amount of mercury evaporating. The mercury evaporating must evaporate in a saturated state, so that by consulting a saturation pressure temperature curve for mercury, the pressure of evaporating mercury is known. The pressure of the condensing mercury vapor can only be different from this due to superheat. If a calorimetric measurement were made on the thermometer well, the heat represented by superheat could be determined. To do this the temperature is measured at a point where there is a natural balance between evaporation and condensation. From information on the heat loss of surfaces, the energy passing through

the glass can be calculated. The superheat at this point is found to be about 20 deg. cent., so that at most points in the condensing chamber the degree of superheat is probably negligible. In the regions of high ionization density, the recombination on measuring surfaces would produce the same indication as superheat.

The relation between saturated mercury vapor pressure and temperature is given in Fig. 7., and the observed vapor pressures for a 20-ampere glass tube

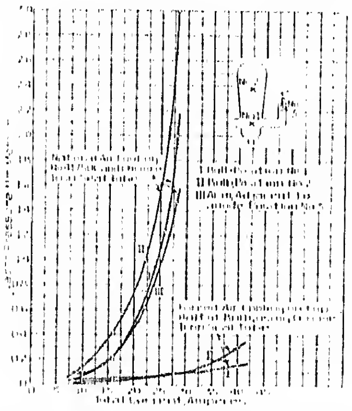

FIG. 8—VARIATION OF VAPOR PRESSURE WITH CURRENT IN GLASS RECTIFIER

are given in Fig. 8 and Fig. 9. By comparison with Fig. 1, it appears that minimum arc-drop corresponds to about 0.1-mm. pressure for either natural or fan cooling, using the pressures obtained for the neighborhood of the anode arms. Other things being equal, the greatest efficiency will be obtained with a vapor pressure of approximately 0.1 mm. or corresponding to a temperature for saturated vapor of 82 deg. cent.

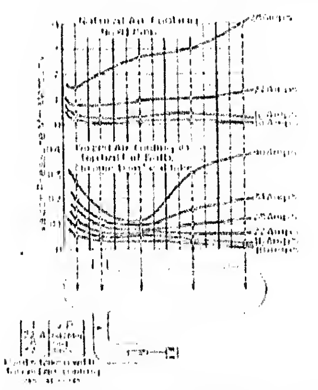

FIG. 9—VARIATION OF VAPOR PRESSURE WITH LOCATION IN GLASS RECTIFIER

Fig. 2 shows a slightly lower drop at 90 deg. cent. and a lower current. The tube had to be heated to secure this temperature at a current of six to eight amperes whereas the 90-deg. curve is higher than the 80-deg. curve under full load conditions.

Similar pressure measurements can be made on iron tank rectifiers by providing them with glass windows on which condensation and evaporation can be observed. The difficulty in this case is to secure the proper location for the windows but valuable information is likely to be secured in any case.

In running such pressure tests, it has been observed that the condensing chamber may run 20 deg. to 30 deg. cooler than the saturation temperature. Several obvious explanations for this phenomenon do not seem to apply. For instance, a temperature gradient might exist in iron or glass. But such a gradient is calculable from the known loss per unit of area and heat conductivity and calculations indicate fractions of a degree. There is always a loss at a boundary where heat is transferred from one material to another. The amount of this drop is known and small for the conditions employed, since heat need only be conveyed to a thermometer well. The amount of mercury vapor condensing and evaporating from the surface is several times the amount required to deliver heat by condensation and raise the parts in question to the temperature of the interior.

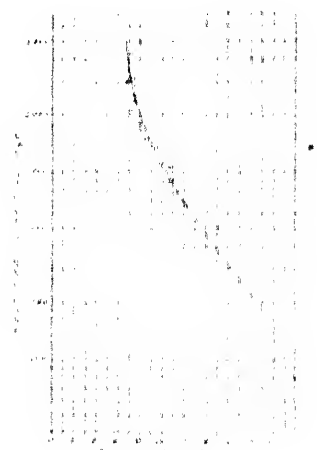

FIG. 10—ARC-BACK CURVE FOR 10-AMPERE 200-VOLT GLASS RECTIFIER—NATURAL AIR CIRCULATION

The most reasonable explanation appears to be that the fixed gas which evacuation has failed to remove from the rectifier is entrained by the mercury vapor and carried to the walls of the condensing chamber. Since these gasses cannot condense, they remain as a cushion of dead gas through which the mercury vapor must diffuse before it can condense. By assuming a reasonably small value for residual gas pressure and calculating how thick a film this gas would make if compressed against the condensing surfaces at the pressure of the mercury vapor, a value is obtained which is of the proper order of magnitude to account for the observed temperature drop from the mercury vapor to the condensing surface.

ARC-BACK

The mechanism of conduction has been developed in advance of the mechanism of failure since the failure is merely conduction at the wrong time. Before setting up what is believed to be the correct theory, some of the observed facts may be described.

Observed Arc-Back Data

Fig. 10 is an arc-back curve of a standard 10-ampere, 200-volt mercury arc rectifier. Previous tests had been made of the dotted low voltage portion. The curve

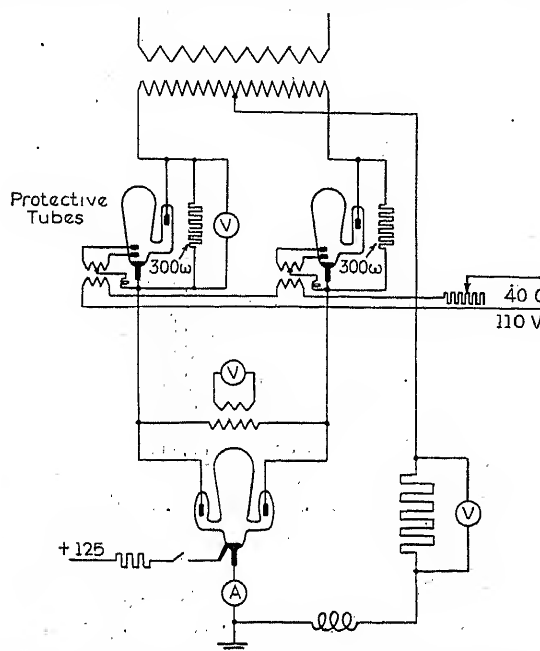

Fig. 11—Arrangement of Rectifiers for Arc-Back Tests

therefore represents actual test results up to 4300 volts. Other tests were made to 10,000 volts, but extraneous factors prevented consistent results. The method of making such tests is to connect three rectifiers, as shown

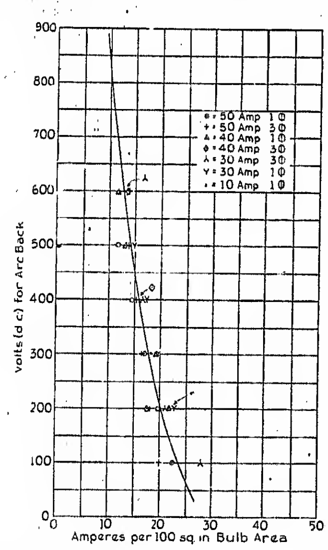

Fig. 12—Composit Arc-Back for Glass Tubes Natural Air-Cooled

in Fig. 11. Two are used for protective purposes and have auxiliary anodes from which a cathode spot is continuously maintained. The circuit to each anode of the tube under test is carried through a protective tube shunted by resistance. As long as rectification is practically perfect, there is little current in the shunting resistances and the full burden is borne by the tube under test. If a failure to rectify occurs, the reversal current flows through the shunt resistance which limits it to such a value that the rectifier under test is not in-

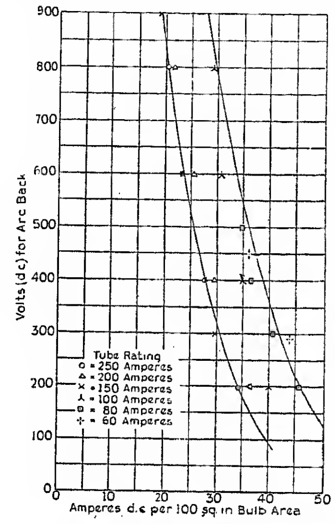

Fig. 13—Composit Arc-Back Curve for Glass Tubes Fan-Cooled

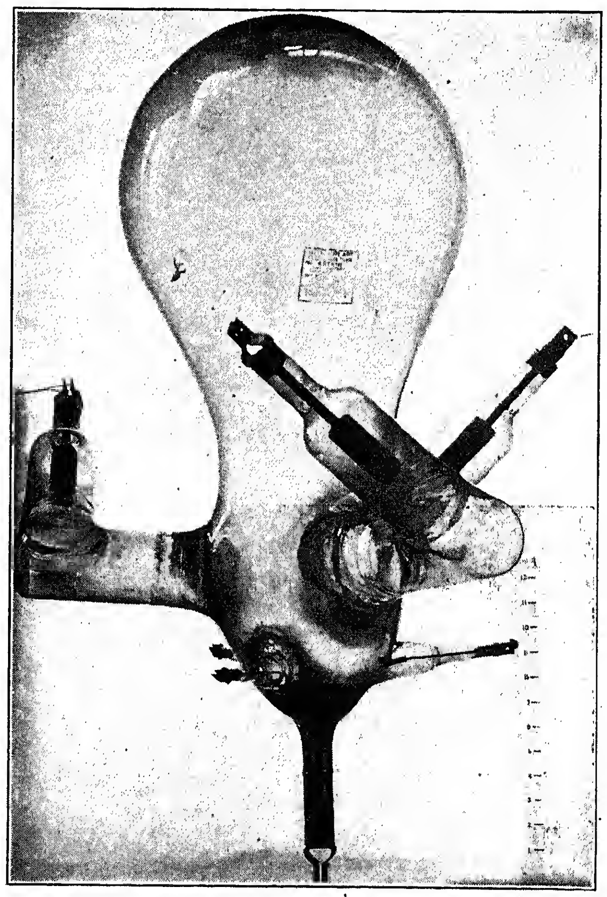

Fig. 14—250-Ampere, Three-Phase 500- to 600-Volt Multiple Mercury Arc Rectifier Tube

stantly destroyed. The protective tubes are larger and better cooled than the tube under test and so do not give way. Such tests are most readily made on glass tubes because in the past they have been the only ones that could be depended upon to repeat themselves.

Fig. 12 gives the arc-back curve of a whole series of tubes of similar shape reduced to the performance per 100 sq. in. of bulb area. Fig. 13 gives similar data for tubes cooled by a fan. Two forms are represented. The left-hand curve is for tubes having a

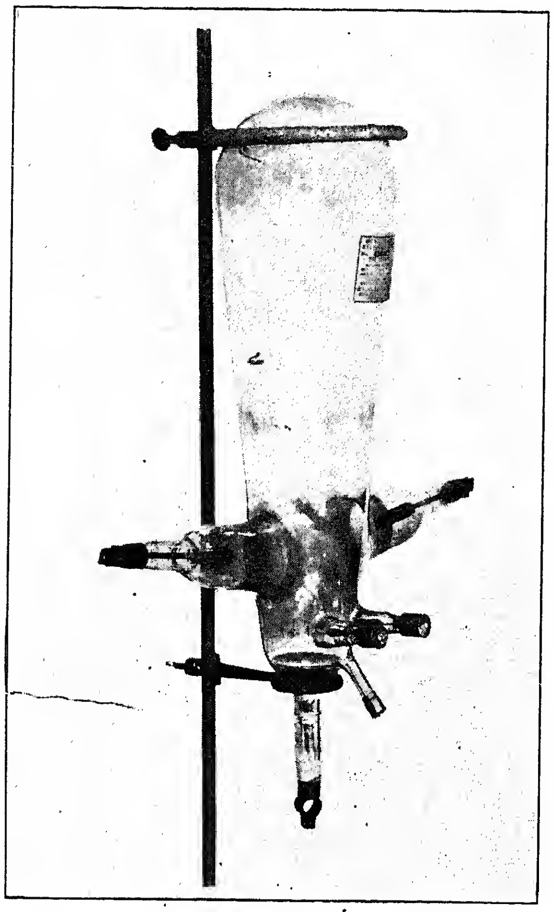

Fig. 15—150-Volt Mercury Arc Rectifier Tube

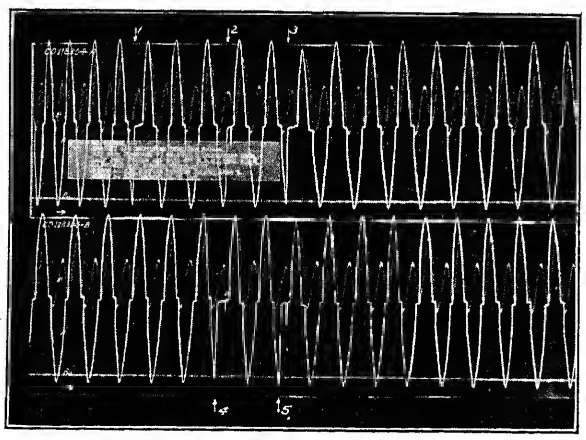

Fig. 16—Oscillogram of Arc-Back taking Place

modified hour glass form, such as Fig. 14. The right-hand curve is for straight sided tubes such as Fig. 15.

As in the arc-drop measurements, a tube of greater section gives superior results. More intense cooling gives a further shift of the arc-back curve to the right. Curves are not available because of the larger power required since the tubes were actually loaded up to the point where failure occurred and only 50 kw. were available for the tests.

Derived Arc-Back Curves

Of course it is not very satisfying to know the limitations of a given rectifier without knowing the reasons, because it is always possible that some insignificant change might multiply the output several fold with no increase in cost of manufacture. In searching for

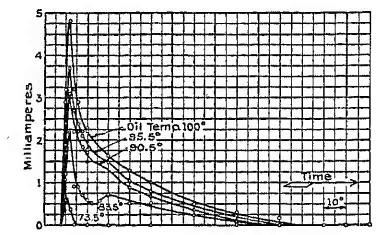

Fig. 17—Inverse Currents in a Glass Mercury Arc Rectifier

reasons, the first steps were naturally empirical, feeling the way. Rectifiers were operated with varying amounts of inductance in the a-c. circuits. These failed at a lower d-c. output voltage which corresponded to nearly the same voltage on the a-c. lines; that is, the peak inverse voltage was the same. Two tubes connected like the protective tubes in Fig. 11, but without the shunting resistance, carried more load than two tubes each rectifying both half waves. These bits of evidence tended to show that the failure occurred

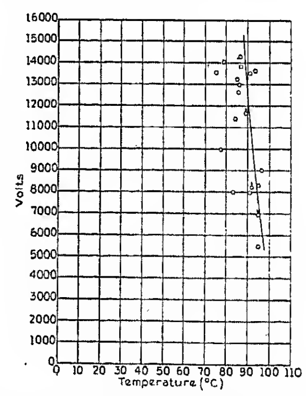

Fig. 18—Breakdown of Rectifier without Arc as Function of Temperature

at the inverse voltage peak, but conclusive evidence of this was wanting until one tube came under test which arced so consistently that it could be caught in the act by an oscillograph. Fig. 16 is a record of actual arc-back taking place. It appears that the failure occurs at or near the voltage peak so that conditions at that time should yield the explanation for arc-back.

Fig. 17 is a record of inverse currents at different points in the inverse half-cycle, and shows that at the

negative inverse peak there is practically no ionization present, even at temperatures a good deal higher than those used in operating rectifiers. It should therefore be possible to test for breakdown in a tube not operating at all, provided the pressure conditions are duplicated, and have the results apply to an active rectifier. Fig.

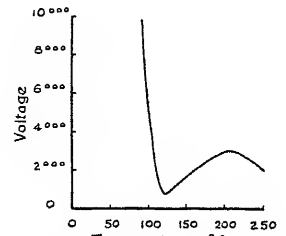

FIG. 19—BREAKDOWN OF MERCURY VAPOR

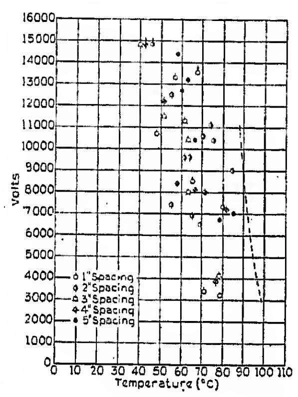

FIG. 20—BREAKDOWN OF MERCURY VAPOR FOR VARIABLE ELECTRODE SPACING

18 shows the breakdown voltages for a considerable variety of tubes as functions of temperature. Fig. 19 produces Fig. 18 to higher temperatures. Fig. 20 gives corresponding data for a special tube having movable electrodes. From these figures it appears that a considerable variety of rectifiers break down at almost exactly the same voltage and temperature. Within these limits the electrode spacing is immaterial. The special movable electrode tube could not be exhausted so well as the others and it accordingly breaks down at lower temperatures, but as perfection is approached the points of failure approach a common curve.

If these breakdown data are significant, it should be possible to check the breakdown curve by means of the current voltage arc-back curves reduced to pressure temperature abscissa by means of the pressure temperature measurements which have been described. Fig. 21 shows such a comparison. An envelope is formed by curves A and B which enclose the breakdown points obtained with no arc in the tube. The other curves are the actual observed arc-back curves for three sizes of tubes reduced to a pressure basis.

The envelope in Fig. 21 is rather a wide one but at least the elements of constructive design are present.

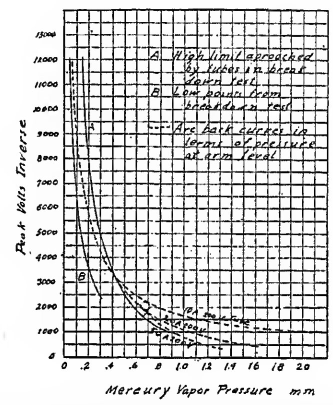

FIG. 21—COMPARISON OF BREAKDOWN AND ARC-BACK CURVES FOR MERCURY ARC RECTIFIER TUBES

The width of the envelope is a measure of vacuum technique. The relation between pressure and temperature of the cooling medium is a matter of thermodynamic technique. It is predicted that within five years there will be less mystery about the design of a mercury arc rectifier than now enshrouds the limitations of commutating machinery.

NOTE: The physical mechanism of the breakdown between electrodes at low pressures has been roughly indicated by such investigators as J. J. Thompson, "Conduction of Electricity through Gases," and J. L. Townsend, "Electricity in Gases." A more detailed study of what happens when a cathode is formed on a conducting surface is being made by Dr. I. Langmuir and should be published in the near future.

Current Collection from an Overhead Contact System Applied to Railroad Operation

BY S. M. VIELE[1]

Non-member

Synopsis.—This paper discusses, from a non-mathematical standpoint, certain factors which should enter into the design of an overhead contact system on an electrified railroad. It emphasizes desirable features, mechanical and structural, and indicates practical limits which conditions will permit in the attainment of these features.

Tests made by the Pennsylvania Railroad with slow-motion photography are outlined. These tests were made to determine operating conditions of the catenary construction with two different types of supporting attachments, over both curved and tangent track. Deflections and oscillations were studied in order to bring out the most productive sources for future study and improvement of the design in respect both to elimination of wear and to maintenance of uniformly good current collecting qualities.

THE use of low potentials on a contact system permits the installation of the contact conductor in such a position that, although within relatively easy access to the public, in general, it is not an undue hazard to them. The use of higher potentials on such systems has carried with it increased hazard, which has necessitated the isolation of this conductor at distances which materially reduce the hazards of accidental contact.

Isolation has usually taken the form of an overhead contact conductor along which a shoe or wheel is carried by the locomotive or car. The distance from the rail to the contact wire varies through relatively wide limits due to the exigencies of the conditions to be met along practically all railroad rights-of-way. Overhead bridges, tunnels, and other obstructions require construction at heights which will permit little more than actual clearance for the rolling stock, whereas reduction of hazard to trainmen and the public generally requires a greater clearance than that usually obtainable through obstructed territory.

The height of a multiple-unit car, such as is used in our suburban service, to the crown of the roof is 13 ft., 0 in. (3.96 m.) The height of an electric locomotive of L 5 class is 13 ft., 5 in. (4.09 m.). These dimensions have resulted in our setting a minimum trolley wire height of 15 ft., 3 in. (4.65 m.) in completely electrified territory where steam locomotives are not permitted to move. This minimum trolley height is never used except where the conditions necessitate. It represents conditions in tunnels and is occasionally approximated at overhead bridges.

The installation of a contact system at such an elevation would make approach to the roof of cars or locomotives very dangerous and would not represent an operative condition if used, except in very limited stretches.

In case operation should require an employe on top of the rolling stock for minor repair work, the height of trolley should be 22 ft. (6.71 m.) as this is the minimum height with which it is at all feasible to make even minor repairs. This includes an allowance of about one ft. (0.30 m.) for the increased sag under hot weather conditions. Such a dimension for trolley height has been adopted for suburban territory. It is not an ample clearance but some work can be done if proper care is taken. At the same time, my own experience does not permit me to say that it is a position of mental comfort. Two feet more, or a total contact height of 24 ft. (7.31 m.) is, from a clearance standpoint, a very much better proposition. This additional two-ft. (0.61 m.) clearance above a minimum of 22 ft. (6.71 m.) is very hard to obtain and in some cases almost impossible in urban districts, owing to the requirements placed for city grades, adjacent property conditions, etc. In open country, where there are relatively few overhead bridges, the 24 ft. (7.31 m.) can be obtained and such a standard set.

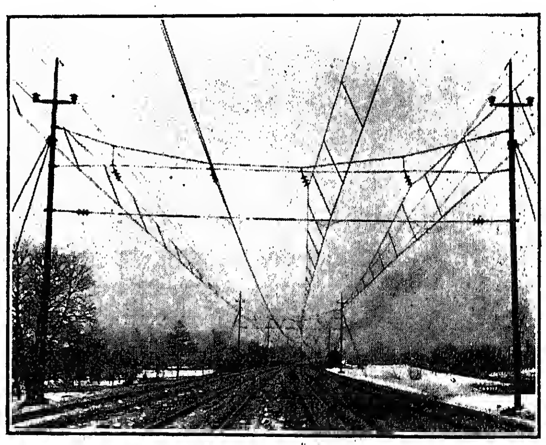

FIG. 1—VIEW OF STANDARD CONSTRUCTION ON CURVED TRACK

Steadying against side-sway on standard tangent track is accomplished in a similar manner

The distance from rail to contact wire will vary from about 15 ft. (4.57 m.) to approximately 25 ft. (7.62 m.). This variation requires that the device which carries the actual contact member and bridges the space between the locomotive or car roof and the contact wire shall be capable of operation at varying heights over a

1. Asst. Electrical Engineer, Pennsylvania Railroad.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

range of some 10 ft. (3.05 m.). Its operating range should permit of its minimum height position being about three in. (0.08 m.) below the minimum operating height position and it should be capable of extending some 6 in. to 12 in. (0.15 m. to 0.30 m.) beyond its highest operating position.

Pantographs, carrying collecting shoes, have been exclusively used by the Pennsylvania Railroad for this purpose, for high voltage service. We have two broad classifications for pantographs, depending upon the equipment to which they are to be applied, *i. e.*, locomotives and multiple-unit cars. The multiple-unit pantograph is a single shoe device of relatively light construction, whereas the locomotive pantograph is heavier and carries two shoes. The weights of these equipments are of the following order:

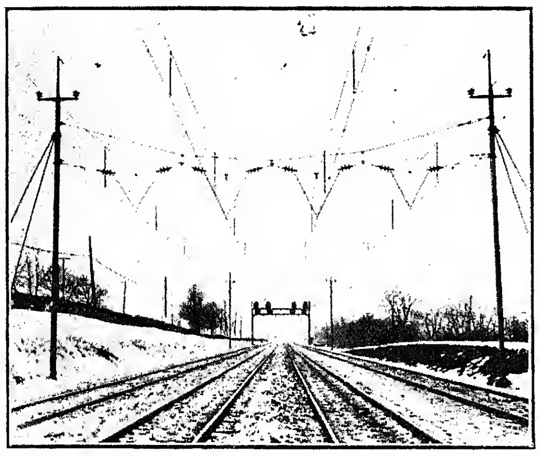

FIG. 2—VIEW OF SPECIAL CONSTRUCTION ON TANGENT TRACK

Steadying against side-sway on special curved track is accomplished in a similar manner

	Pounds		
	Gross	*"Live"	Shoe
Locomotive.......	1400 (635 kg.)	243 (110 kg.)	33 (15 kg.)
Multiple unit......	710 (322 kg.)	100 (45 kg.)	14 (6.3 kg.)

*Shoe and extensible frame work

In both types of equipment, the "live" weight is carried by the journals of a rotative shaft at each end of the pantograph, the two shafts having connected thereto the bottom members of the pantograph movable framework, which members are held in supplementary angular relation with the base of the device by bell cranks and interconnecting links. In all operating positions, the weight of the "live" parts is eccentric to the shafts, which produces a torsional moment on the shafts which varies in amount throughout the entire operating range. This torsional moment is counterbalanced with helical springs, in tension, applied through chains operating over cam surfaces, the latter being attached to each end of each shaft.

The necessity for a small collapsed height of pantograph does not permit of a very large radius for the cams nor a large elongation of the springs and, consequently, the spring tensions are material. This spring tension is used to support the pantograph in all operating positions and to provide the force required for upward acceleration of the shoe and frame work, as well as to overcome the frictional resistance to upward movement.

Collection requires that the force of contact should be as near constant as is feasible and that the friction of vertical movement of pantograph should be relatively small. It becomes evident that this is not a simple problem when it is considered that the spring tension on a multiple-unit pantograph for operation on trolleys at 22-ft. (6.71 m.) elevation is 460 lb. (208.6 kg.) for the minimum operating height and 150 lb. (68.0 kg.) for the maximum operating height, in each of four springs, and that the weight of the moving members is of the order of 100 lb. (45.4 kg.), the latter being variably applied. A pantograph operated vertically, on a stationary block, exerts 18 lb. (8.2 kg.) of upward force under slow motion conditions, with a total variation of force of about 10 per cent. Downward motion produces approximately 10 per cent additional variation.

The above figures are based upon favorable conditions. If sleet accumulates on the framework, it does not take long until sufficient weight is added to overcome the 18 lb. (8.2 kg.) of upward force. Wind loads have affected the operation of some of the early designs to a sufficient extent to actually drop the mechanism.

It has been frequently asked why the upward pressure should not be increased so as to have a larger working margin. Two major limitations exist.

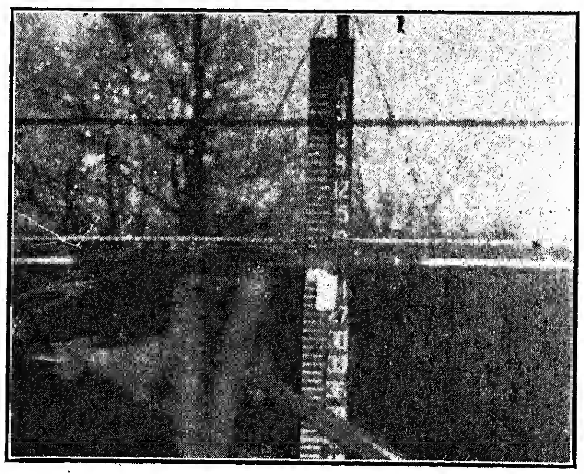

FIG. 3—ENLARGEMENT FROM SLOW-MOTION PICTURE

This shows the locomotive pantograh shoe parting contact at the trailing end of a wire splice.

In case the sum of the pressures of all pantographs on a given span of contact wire approaches the weight of construction lying immediately adjacent to the contact plane, columnar instability of the overhead results. If the pressures are increased sufficiently, the contact wire will occasionally turn over, exposing the contact

wire attachments to blows from the passing pantograph.

The wear on shoes and the contact wire itself is, for a non-lubricated contact, a function of the mechanical abrasive effect varying with pressure, and the pitting and burning effects caused by current flow.

The most economical pressure apparently varies with the current collected from a single shoe. As the current value decreases, lighter pressures can be advantageously used. This is fortunate, as otherwise it would be difficult to operate some four to six multiple-unit pantographs in a given span without increasing the weight of actual contact system or providing special stiffening attachments for the contact wire.

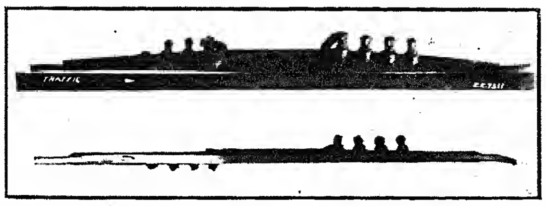

Fig. 4—Close-Up of Badly Worn Wire Splice

This picture shows the occurrence of wear at the approaching end and pitting action at the trailing end of the splice

The force required for downward acceleration of the "live" parts of the pantograph is the sum of the upward thrust of the shoe plus an increased reaction to cause downward acceleration. This sum must not reach a value which will permit the turning of the contact wire. It follows that the upward acceleration forces which are permissible in the pantograph are less, by an amount necessary to produce maximum downward acceleration, than those which will be sufficient, under any conditions, to cause overturning of the contact wire. It should be borne in mind that the downward accelerating forces vary with speed of traffic, gradients, changes of sag, etc., and a suitable margin must be left between these totaled upward pressures and the weight of the construction adjacent to the contact plane.

The pantograph has a natural period of vibration, in a vertical plane, if it is considered that it be pulled down at the same rates at which it will rise under the application of forces inherent in the design. This periodicity of vertical vibration is an inverse function of the mass involved in the "live" parts and the friction of operation of the pantograph mechanism, and a direct function of the actuating force (the latter limited by maximum permissible wire pressures). Commercial designs vary but are of the order of from 40 to 70 beats per min. The latter figure represents very careful attention to the entire pantograph design.

The more rapid oscillatory designs are of advantage in obtaining better collection on any given overhead design. At the same time, this periodicity can be and is improved by the secondary supporting of the shoe itself, by springs which produce pressures well above and below the forces applied through the main framework. With the reduced mass to be vibrated and with forces approximating those applied through the main framework, the shoe periodicity is much higher but, of course, of very low relative amplitude.

What is desired is a continuous contact with the trolley at as near a uniform pressure as is feasible. The nature of the overhead system involves major changes of elevation of the contact system, necessitating grades for transition between these different elevations; there are changes of elevation of the contact plane in a given span; the weight of construction is not uniform and cannot be made so; construction has to be utilized in the contact member which represents very abrupt changes in weight; all of which produce changes of contact pressure which show up in increased deterioration of the overhead contact member, and of the shoes. The eventual result of satisfaction with operation is not a matter solely of overhead design or of pantograph design but a result of coordinated effort in both designs.

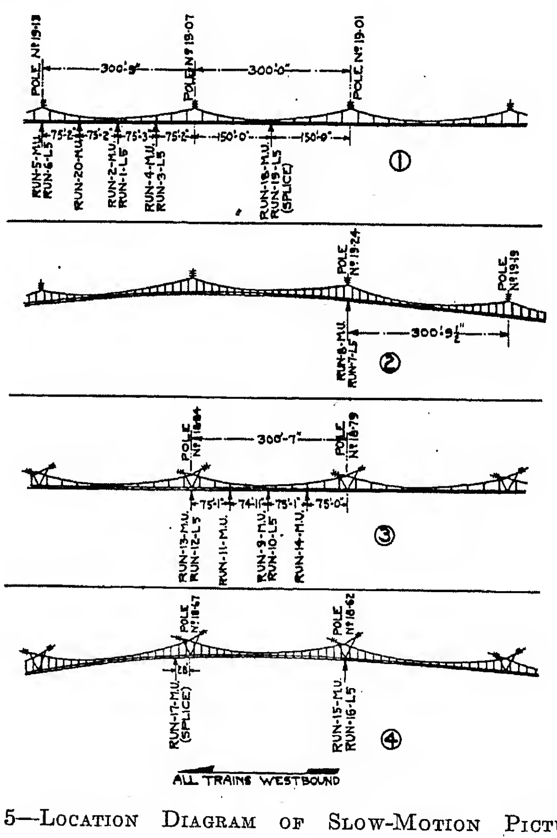

Fig. 5—Location Diagram of Slow-Motion Pictures

1. Standard tangent construction
2. Standard curve construction
3. Special tangent construction
4. Special curve construction

A live resilient pantograph operating on a poorly designed overhead system will necessarily not give as satisfactory results as would be produced with a better design of overhead. The same general statement may be made with reference to the design of the overhead system itself.

A pantograph shoe is limited in length (about four

ft. (1.22 m.) transverse to the track), and if the overhead is not properly located over the track, or if the catenary is permitted to sway under wind conditions to a sufficient extent, the shoe passes to one side of the contact wire, rises to an elevation above the contact wire and practically always catches in some part of the overhead, with the result of damage to the pantograph sufficient to render it inoperative and occasionally materially damaging the overhead.

Reduction of occurrences of this nature on tangent track may be obtained by shortening the span length or by means of steadies applied at the support points. The latter is the more economical procedure. Spans may be installed with little trouble of this nature, of the order of 285 ft. (86.87 m.) in length, with proper burning of the vital members of construction in case of flashover of insulators, and in case of damage, the positioning of members such as to clear pantographs in as many cases as possible.

The trolley construction used in the Broad Street-Paoli district, carrying 11,000 volts single phase, consists of a ½-in. (12.7 mm.) steel messenger, from which is suspended, by 3/16-in. by 1-in. (4.75 mm. by 25.4 m m.) straps at 30-ft. (9.14 m.) intervals, a 1/0 round copper auxiliary wire, from which in turn is suspended, by clips at 15-ft. (4.57 m.) intervals, a 3/0 grooved bronze contact wire. The contact and auxiliary wires lie parallel to one another in a vertical plane. The connections between these two wires "break joints" with the connecting hangers lying between the

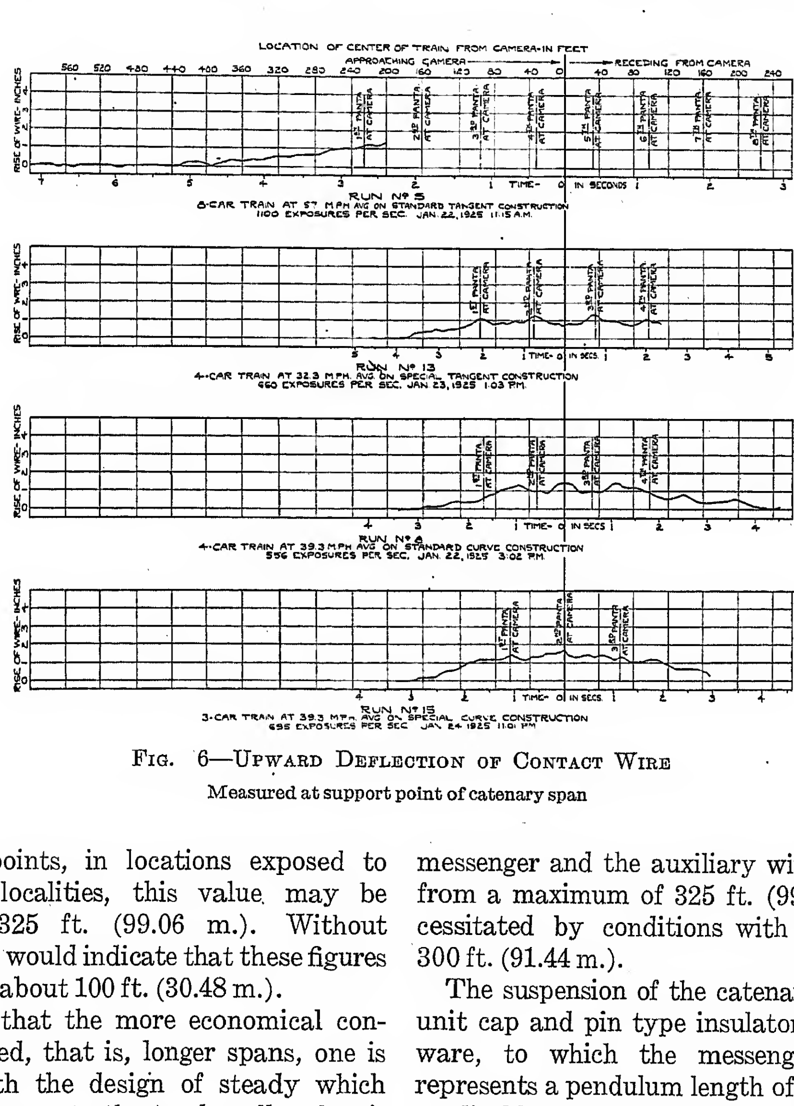

Fig. 6—Upward Deflection of Contact Wire
Measured at support point of catenary span

steadies at support points, in locations exposed to wind. In protected localities, this value may be increased to about 325 ft. (99.06 m.). Without steadies, our experience would indicate that these figures should each be reduced about 100 ft. (30.48 m.).

On the assumption that the more economical construction should be used, that is, longer spans, one is immediately faced with the design of steady which will limit motion transverse to the tracks, allow longitudinal equalization of tensions and permit as great a vertical movement of the contact member at the support points as is possible. The above represents the mechanical requirements. Electrical requirements involve the maintenance of potential across the insulators and of suitable clearances. Maintenance requires easy access with suitable working clearances, prevention of messenger and the auxiliary wire. Span lengths vary from a maximum of 325 ft. (99.06 m.) to values necessitated by conditions with an average of about 300 ft. (91.44 m.).

The suspension of the catenaries consists of a three-unit cap and pin type insulator and assembling hardware, to which the messenger is attached. This represents a pendulum length of about 24 in. (0.61 m.) applicable to the messenger. The messenger has five ft. (1.52 m.) of sag in a 300-ft. (91.44 m.) span, which construction produces a total pendulum length at the support point of approximately 7ft., 6 in. (2.29 m.).

The original design did not call for the use of steadies except at a few locations. Operation, however, has necessitated their general installation in exposed locations.

The steady design adopted consisted of a horizontal strand installed between the catenary supporting poles at an elevation six in. (0.15 m.) above the contact wire. This strand was insulated from the poles by three-unit porcelain insulators adjacent to the poles, with a sectionalizing wood stick insulator between the auxiliary wires of adjoining tracks. Attachments were made by a slack two-way jumper from this strand to the auxiliary wire. This construction reduced what may be termed "pantograph derailments" to a radical degree. The disadvantages of this design were:

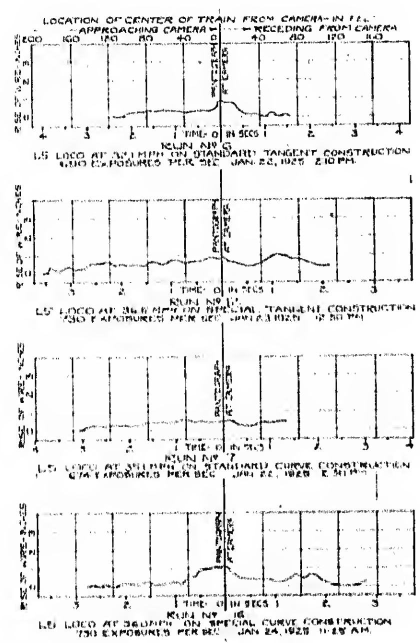

FIG. 7—UPWARD DEFLECTION OF CONTACT WIRE
Measured at support point of catenary span

a. The wood sticks used for sectionalizing the track trolleys do not have potential impressed across them except under conditions of a de-energized adjacent track, which condition usually develops their failure, if any, at the most inopportune time.

b. Small working clearances for certain repair operations.

c. Periodic cleaning, varnishing, and general overhauling of the wood sticks.

d. The impassability of one or more tracks in case of steady span failure, on account of portions of steady span construction hanging down below the elevation of the contact plane.

e. Small upward deflection of the contact wire at the support point.

In the effort to improve catenary support conditions, a new form of support was laid out which, in my opinion, reduces to a material degree the disadvantages of the previously described steady.

The standard form of back guyed poles, cross catenary, and body span member were used; however, instead of suspending an insulator string directly over the track for attachment of the messenger, a string was placed each side the center line of each track. Connected between these insulators is a short length of cable approximately eight ft. (2.44 m.) long, with sufficient sag in it that when drawn downward at its center, it forms the two legs of an obtuse triangle with its apex about 30 in. (0.76 m.) below the body member, this point being used for the attachment of the messenger. The ends of the insulators nearest the center line of the track have a second attachment with members running to a common point and attached to the auxiliary wire. In appearance, the construction forms a letter "V" with the auxiliary wire attached at the bottom apex and the upper ends of the legs of the "V" attached to sides of the obtuse triangle at the lower ends of the insulators. This construction fixes the position transversely of the messenger, and eliminates the pendulum length of the messenger suspension. It places all insulators between trolley and ground, thereby retaining potential across them. It introduces a short section of cable between the messenger and the insulators, and consequently, an arc from a flashed insulator is removed from the messenger and taken by the messenger supporting member.

A parallel path for current supply to an arc at the insulator is provided by the secondary hanger connecting between the auxiliary wire and a point adjacent to the live end of the insulator. This, we consider,

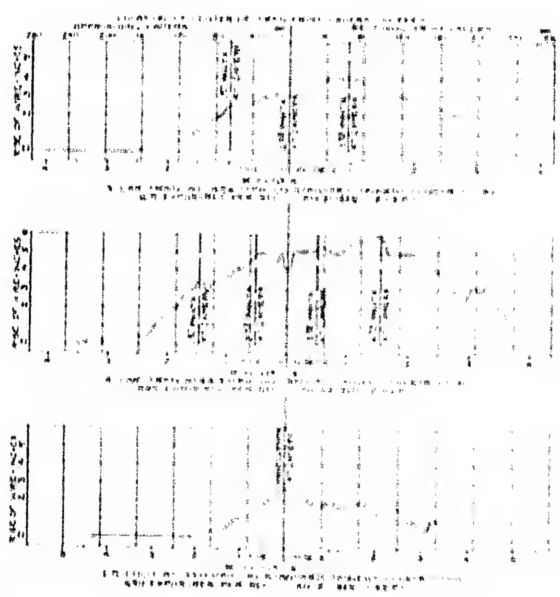

FIG. 8 UPWARD DEFLECTION OF CONTACT WIRE
Measured at entering quarter point of catenary span

will reduce the localized annealing of the messenger under flashed insulator conditions, as there is provided a shunt path for the current flowing from the trolley and auxiliary wires to the point of arc contact with the catenary supporting member.

The two members forming the lower "V" converging on the auxiliary wire leave the clearance between tracks as a maximum at the contact wire elevation, with the

minimum clearance existing at the insulators, just below the body member.

Tests with this construction loaded horizontally and transversely of the tracks indicated greater displacement at the support point as compared with our usual form of horizontal strand steady. Displacement at the center of span with the two forms was within one per cent of one another. The total displacement of the special form of steady at the support point was approximately one-half of that obtained in the center of the span.

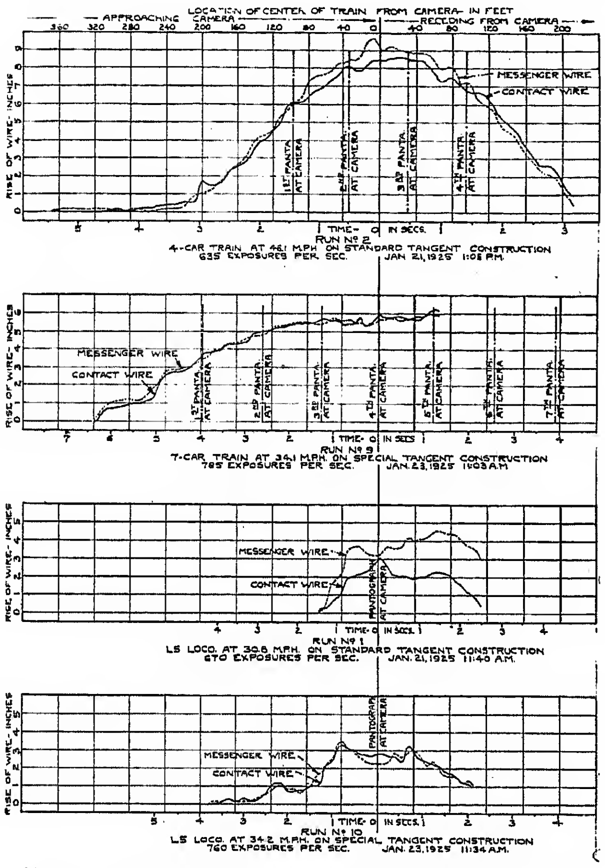

FIG. 9—UPWARD DEFLECTION OF CONTACT WIRE
Measured at center point of catenary span

In thinking of catenary construction, most engineers consider that contact is made with the overhead conductor in practically a uniform plane and that there is little or no upward displacement with pantograph passage. Even among engineers who have watched such things, the impression is that the deviation of the contact wire from a uniform plane is a matter of a few inches and that the wave of this deviation follows closely the position of the pantographs.

If we assume the messenger as carrying practically all of the weight of construction in a given span and that this weight is fairly uniformly distributed, we obtain an approximation of a catenary curve. The direction of the tension in the messenger makes an angle of varying magnitude with the upward thrust of the pantograph. At the point of maximum sag in the messenger, the tension in the messenger and the thrust of the pantograph are at right angles to one another; as the support points are approached, this angle decreases and is a minimum at the support point. The application of a vertical force applied at the center of sag, therefore, has a maximum effect producing upward displacement of the trolley wire, on account of the fact that there is no vertical component of tension at that point, but only horizontal tension, which is constant throughout the span; whereas at other points than the center of sag, a vertical component of tension exists, which, opposing the upward shoe pressure, reduces the upward displacement of the contact wire. There is little or no displacement of the construction as a whole at the support points such as occurs at the center of sag of the messenger. Displacement at the support point is almost exclusively displacement of the contact wire in relation to the messenger, in other words, a closing up of the space normally existing between the messenger and contact wires.

This upward movement of the catenary which takes place at points in the span is evidently brought about by the ease of equalization of messenger tension to adjoining and successive spans. The load supported by a given messenger tension being reduced by pantograph pressure, equilization of tension demands a reduction of sag in the span whose load is so reduced. If this statement is correct, then an increase of total pantograph pressure, whether applied by a single pantograph or by increasing the number, should increase the upward deflections. This result is confirmed by trials.

From what has so far been said, it is to be inferred that there is a major oscillation imposed upon the main framework of the pantograph, whose periodicity is a function of span length employed and an inverse function of the speed of the rolling stock.

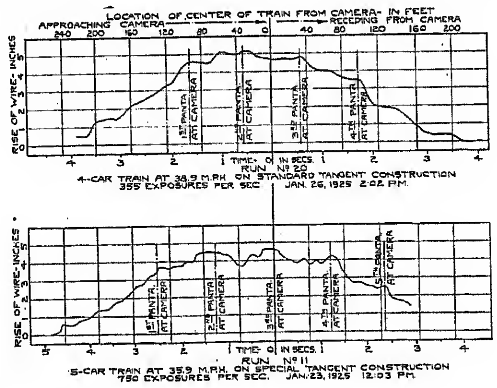

FIG. 10—UPWARD DEFLECTION OF CONTACT WIRE
Measured at trailing quarter point of catenary span

The oscillation of the contact wire travels ahead of the pantograph with various irregularities or harmonics imposed on it. Support points tend to become nodes of the wave. Changes of mass, usually splices, trolley wire intersections, or section breaks retard the propagation of these oscillations.

A traveling wave impinging upon a section of greater mass than that employed in the adjacent section is damped to a material degree. As the wave reaches the increased mass, the change of elevation of the contact plane does not take place as rapidly as it did in previous sections of the contact wire and there is produced, locally, a gradient at the approach to such mass of greater slope. This greater slope produces increased pressure between the shoe and the trolley wire which accelerates the shoe downward and the contact wire upward. The pressure produced between the shoe and the contact wire is such as to accelerate the two members in opposite directions at velocities sufficient that they over-travel and contact is momentarily lost.

Such loss of contact is usually caused by definitely establishing an out-of-phase relation between the oscillation of the shoe and the contact wire. There are two other causes of loss of contact occasionally present, however, one being the result of insufficient range of movement of the shoe supports and the other the inability of the shoe to follow in time the periodicity of oscillation of the contact wire.

Taking the more usual case of conditions existing at the time contact is lost, that is, an out-of-phase relation between the oscillation of the shoe and contact wire, the succeeding occurrences are that as the shoe and contact wire again approach one another, the phase relation of their oscillations is still materially displaced. Contact is made with a pressure increased above normal, due to the vertical velocities present, and excessive wear takes place in these areas.

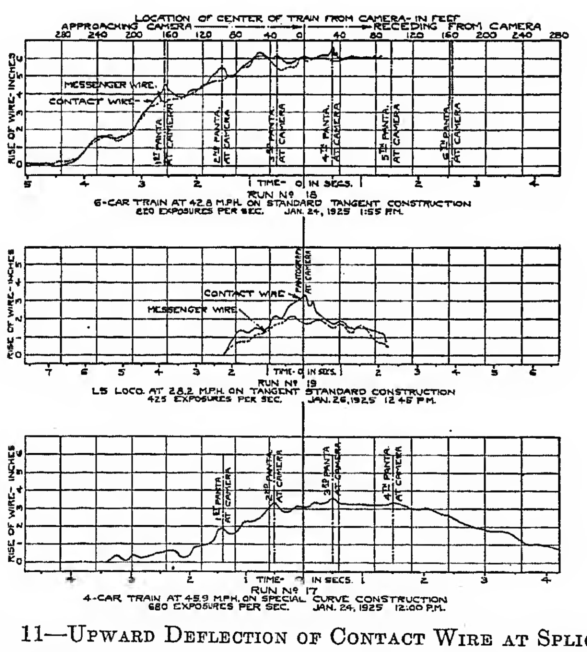

FIG. 11—UPWARD DEFLECTION OF CONTACT WIRE AT SPLICES

Runs 18 and 19—New splice located at center point of catenary span
Run 17—Old splice located 28-ft. beyond catenary support point

Such effects are well illustrated by a splice 24 in. (0.61 m.) long, weighing 3½ lb. (1.59 kg) after a number of years of service. On the entering end, the splice is smooth and bright with a well worn contour; near the middle it shows little deterioration of any nature; at the trailing end, there is practically no wear but a material reduction of section due to pitting and burning. On the wire one foot removed from the trailing end of the splice, there is severe wear and reduction of section.

In so far as splices alone are concerned, these conditions may be corrected, as experience with a splice

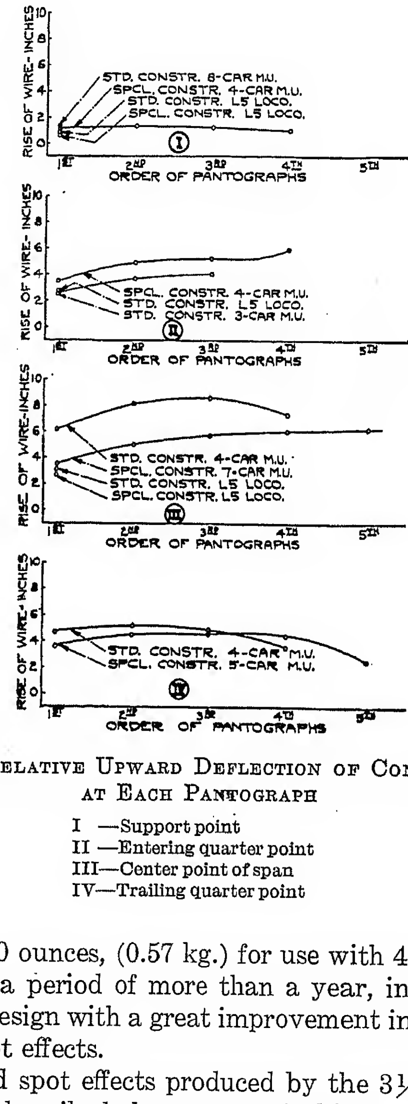

FIG. 12—RELATIVE UPWARD DEFLECTION OF CONTACT WIRE AT EACH PANTOGRAPH

I —Support point
II —Entering quarter point
III—Center point of span
IV—Trailing quarter point

weighing 20 ounces, (0.57 kg.) for use with 4/0 contact wire, over a period of more than a year, indicates an adequate design with a great improvement in reduction of hard spot effects.

The hard spot effects produced by the 3½ lb. (1.59 kg.) splice described above are typical in a general way of hard spots produced by other items or types of construction.

If wood section breaks, usually about six ft. (1.83 m.) long, are used in high speed territory, similar results may be expected, but of very much augmented degree.

The supporting attachments of the contact wire itself may produce similar or worse results. With the attachment of the contact wire directly to the messenger, each hanger becomes a point of increased mass, which, in amplitude of upward movement with pantograph passage, tends to lag behind the construction immediately preceding it. This action produces a hard spot of initially small importance but, as service

progresses, the contact wire may be slowly deformed or kinked immediately ahead of the attachment, with the severity of the hard spot gradually increasing.

This result is the product of a number of intimately related conditions, such as size of contact member, shoe weight, and normal operating pressure, weight of hanger and its location in the span, the weight of messenger and, particularly, operating speeds.

Such a construction with a single contact wire will not operate satisfactorily with the pressure and weights of shoes and with the weights of construction usually used, except at speeds less than those employed in normal railroad operation.

Yard service is slow speed service and such construction at these speeds is satisfactory and is used in yards, as it represents a material saving in initial cost of construction.

Suspension of the contact member directly from the messenger has been attempted with hanger designs intended to correct the conditions outlined above. The use of loop hangers on systems in which the normal current values and short-circuit conditions do not approximate those necessarily involved on a major electrification, is not here criticized, though the writer is of the opinion, from our past experience, that the use of such hangers is not applicable to conditions of major electrifications.

The contact made by such hangers with the messenger wire is of such a nature that, under large current flow conditions, annealing and occasional burning of the messenger wire may be expected.

The messenger wire is a very vital part of the catenary construction, not only on the basis of its usual function, but on the basis of what is involved in repairs in case of its damage. The importance of this statement may be overlooked and it is wished to emphasize it by explaining that satisfactory current collection at the speeds used necessarily involves a very high degree of uniformity of construction; the higher the speed, the more exacting the requirements.

In case the messenger parts, from whatever cause, the unbalanced tension therein immediately tends to rip the construction to pieces, with the result of broken connections, distorted hangers, kinked contact wire, etc. These results, with decreasing severity, extend each way from the break. Repairs under such conditions are made in successive steps; the first thing is to get the overhead up out of the way of traffic quickly, supporting it in any way possible. Repairs of this nature are necessarily a makeshift and they require that traffic through the damaged area be at a reduced speed. Usually pantographs are lowered and equipment drifts through the damaged area. The successive steps are to position the messenger with the correct sag, to remove and replace temporary construction and to strengthen or replace bent hangers, wire, etc., and finally to position the various connections.

It may readily be realized that, if messenger tension in the damaged area is not lost, the amount of damage to the overhead system, with the various mishaps that occur, is very much less and, consequently, it is possible to restore the construction to a fully operative condition in very much less time.

The pantograph design and its operation on an overhead system bear a very intimate relation to the design of the overhead itself. Pantograph design is a specialized subject which has been localized in the hands of the manufacturers, whereas the design of the overhead has usually been in the hands of the owners of the property or their consulting engineers. While it has been appreciated to some degree that the design of the overhead is also a specialized matter, at the same time I do not feel that its importance in eventual satisfaction of operation is as fully appreciated as it should be.

An increase in the amount of available information on the subject of overhead construction is one of the necessities for eventual railroad electrification.

With this in mind, a study was undertaken some time ago by members of our organization, with the idea of determining and depicting, as far as possible, actual occurrences in the pantographs and in the overhead under operating conditions. This study included a comparison of the design of steady which we have been using for a number of years, with the special design described above.

A section of track was selected in the territory lying between Broad Street Station, Philadelphia, and Paoli, Penn., and a number of spans was equipped with the special support construction referred to. Deflections of the overhead system and movement of the shoes were recorded.

The apparatus for these tests included a high speed photographic camera for the study of the various movements which take place in a span of contact wire. Through the courtesy of W. H. Miner, Railroad Supplies, Chicago, such a camera was obtained, capable of taking, on standard moving picture film, photographs at the rate of more than 1000 pictures per sec., together with auxiliary equipment and a personnel familiar with the operation of the equipment and familiar with the possibilities of depicting occurrences at high speed.

The test apparatus consisted of a high speed camera handling film at speeds from 400 to 1100 exposures per sec., a storage battery for current supply to a shunt motor driving the camera and for use in the projectors, projectors for augmenting natural illumination, and a scale used as a background for the contact wire.

One of the center tracks of four was occupied by a tower car carrying the camera, projectors, and operators, a storage battery and work car, and a steam locomotive. The adjoining track towards the outside of the right-of-way was used as the test track. Outside the clearance lines of this latter track a scale was installed which was used as a determinative background against which the contact wire was to be silhouetted.

The camera and scale were supported at such a height

that the camera lens, midpoint of the scale, and the contact wire under investigation were at the same elevation. In front of the scale and held to it by a string was a weight of about five lb., which weight was attached so that its center of gravity was at the zero of the scale. A tripping cord was arranged so that a pull on it would apply a horizontal force on the weight supporting string and break it, allowing the weight to fall.

The camera and scale were located at designated points in the several test spans and, as the multiple-unit train or locomotive approached, its position and approximate speed were signalled from a point ahead of the test equipment.

The camera mechanism was engaged with the running

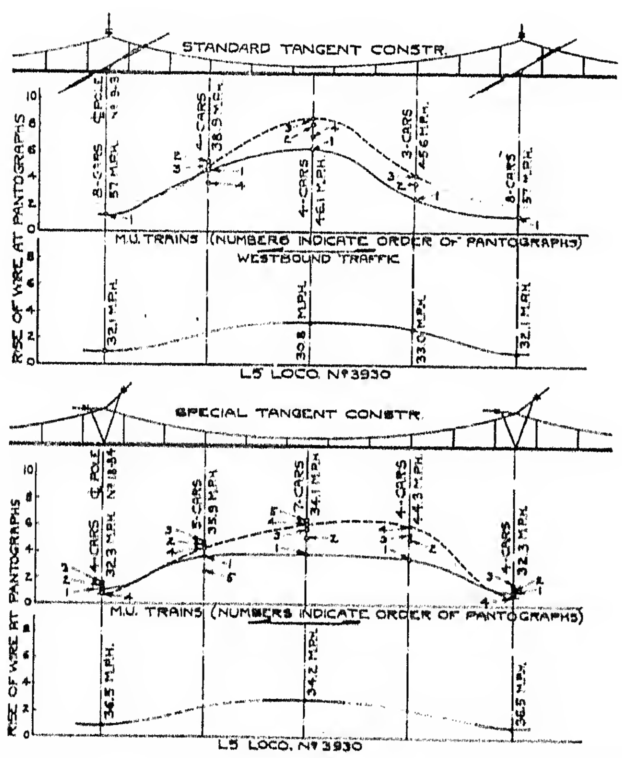

FIG. 13 RELATIVE UPWARD DEFLECTION OF CONTACT WIRE ALONG CATENARY SPAN

motor and the timing weight dropped. Some experimentation was necessary to obtain proper sequence and coordination with the passing equipment, but the arrangement finally worked out very well.

The scale was graduated in inch divisions, with each third inch marked.

The contact wire being located horizontally about midway between the camera lens and the scale, the scale reading is about double the actual wire movement. In working up the data afterwards, it was found that it was not possible to determine when the timing weight started to fall. It was necessary, therefore, to take the difference in theoretical time of fall from the zero to a point on the scale, 39 in. (0.99 m.) from zero, and the theoretical time of fall from zero to a point at a higher elevation, 12 in. (0.30 m.) from zero, as a determinant of the film exposure rate. The time of fall from the 12-in. (0.30 m.) point to the 39-in. (0.99 m.) point, with acceleration started at zero, is two-tenths of a sec.

The exact passage of the timing weight by these points was determined within a few exposures and the intervening pictures counted. This result multiplied by five gives the exposures per second. As the camera was driven by a shunt motor, the exposure rate per second for the few seconds involved was considered constant. Train speed was also considered constant over the test interval. Knowing the exposure rate and the distance between successive pantographs of a multiple-unit train, or the distance between marks on the contact wire, the speed of the pantograph passing the camera field is obtained from the number of exposures between pantograph passages, or from the passage of a single pantograph between the marks on the contact wire.

The distance ahead of the pantograph at which movement takes place was obtained in a similar manner, using the same data given above and the train or locomotive speed.

A number of determinations was made as follows: Deflections at the center, entering, and trailing quarter points of a span and points directly beneath the support points of the messenger. The above trials were obtained for multiple-unit equipment and a portion of them for locomotive equipment, both types of steady construction being photographed.

It was known that a splice in the contact wire caused a heavy flash with pantograph passage, which flash was reduced in intensity with service. A new splice was installed and photographed with current being collected with pantograph passage. The resulting arc fogged the film to such an extent that little may be told from these pictures. A locomotive shoe passing over the splice without current flow, however, tells a story of material departure of the shoes from the contact member. Several pictures were taken on curved construction, which show a much greater flexibility of construction at such locations than exists at similar locations in a span of tangent construction.

The exposures made of each test run were then consecutively numbered in 100 exposure intervals and passed through a projector a number of times until the observer was familiar with the film. Then the position of the contact wire in terms of the scale reading was observed at given intervals of the total exposure, with a notation of the exact picture from which the reading was taken. In cases where there existed some peculiar feature or where it was apparent that harmonics of readable magnitude existed, readings at much closer intervals were made.

These data, converted into distance ahead of the train, were then plotted, the ordinates representing rise of contact wire at the observation point in the span

from its initial position, and the abscissas representing the position of the train with reference to the observation point at the instant of the occurrence of the position of contact wire indicated by the ordinate reading.

These results, shown graphically, are given in the several figures bearing proper title as to type of messenger support, position in the span of the observation point, type of rolling stock, number of multiple-unit cars, traffic speed, and exposure rate.

An analysis of these curves indicates clearly certain conclusions, a portion of which, for a specific design of overhead system, are quantitive. Mathematical conclusions, not included, indicate the basic phenomena to a sufficient extent that usable approximations may be made for construction embodying different weights, span lengths, and types of construction.

Such conclusions follow:

1. That a major oscillation is present in the contact member ahead of the pantographs and travels with the pantographs,

2. That this oscillation is of variable amplitude, depending on its location in the span,

3. That the position of any given point in the amplitude of oscillation has a variable spacing ahead of the pantograph,

4. The amplitude varies with the total pressure imposed by the pantographs in a given span,

5. The amplitude seems to be increased with the distribution through a number of pantographs of a given total pressure,

6. That when distribution of a given total pantograph pressure is made through several pantographs, the pantographs in the central portion of a train experience the greatest amplitude of movement,

7. That the leading pantograph does not have imposed on it as great an amplitude of movement as do all successive pantographs,

8. That the direction of traffic does not materially alter the symmetry of maximum upward deflection of the contact wire,

9. That the gradient to which a pantograph is subjected in passing under locations of depressed contact wire height is augmented by a material gradient imposed by the inherent deflections in the approaching spans and that such augmenting of gradient is of the order of the usually installed maximum gradient, one-half of one per cent; for such transition of elevation of the contact wire,

10. That harmonics of the major oscillation are present each side of the pantographs with relatively minor amplitudes and are apparently damped out at pantographs and do not cause trouble,

11. That the presence of material change in mass of the construction adjacent to the contact plane damps the oscillation and thereby causes relatively severe deterioration due to variation in pressure of contact shoes at such points,

12. That with a given increase of mass necessarily locally employed, shaping of the contact surface will decrease the deterioration at such points,

13. That support points practically represent nodes of the major oscillations, as the amplitude of oscillation is relatively small at such points,

14. That the amplitude of oscillation at the center of the messenger span is maximum with a reduction towards each messenger support point,

15. That the amplitude of movement at the center of the span is almost wholly a movement of the total catenary construction, that is, a movement of the messenger and its suspended construction,

16. That the amplitude of movement at support points is almost wholly a matter of change in spacing of the contact wire and its adjacent construction with relation to the messenger wire,

17. That improvement of hanger construction at points adjacent to the messenger support is possible and desirable,

18. That the use of so-called flexible hangers at the center of span is not necessary and their desirability is doubtful,

19. That flexible hangers adjacent to the support point may be advantageously used if of satisfactory design,

20. That harmonics in the contact wire at positions of change of mass in the construction adjacent to the contact plane and located remote from support points are of high periodicity and considerable amplitude,

21. That such oscillations cause similar oscillations of opposite phase in the contact shoes,

22. That departure of the shoes from the contact wire at such locations are usually the greatest in time and the greatest in amplitude,

23. That the reduction of changes of mass at points adjacent to the contact plane offers the greatest measure of improvement immediately available,

24. That further study of the construction from a trailing quarter point in a span through the support point to the entering quarter point of the succeeding span offers the next most promising step in improvement,

25. That improvement in the secondary supporting of shoes and the obtaining of a greater amplitude of movement of the shoe is probably desirable,

26. That further investigation and study of the tilting action of shoes is necessary and desirable, as there are indications that edge riding of shoes is at times present to a material degree.

Discussion

For discussion of this paper see page 1133.

Catenary Design for Overhead Contact Systems

BY H. F. BROWN[1]

Member, A. I. E. E.

Synopsis.—This paper is intended to outline methods which have been found useful in the design of overhead contact systems where catenary construction is employed, with especial reference to the single catenary construction installed in 1925 on the Danbury Branch of the New York, New Haven, and Hartford Railroad as an extension of its 11,000-volt, single-phase, a-c. electrified zone; and on the New York, Westchester, and Boston Railway on its extension from Larchmont to Harrison, N. Y.

Part I deals with construction over straight or "tangent" track, and is a review of methods and formulas which, while not new, are necessary as an introduction to Part II, which not only includes tangent-chord construction, but deals at length with the design of the so-called inclined catenary and its adaptation to curved track.

THE fundamental requirements of an overhead contact system for high speed railway electrification are:

a. It must be parallel to the track centerline, or nearly so, within prescribed limits. When changes are necessary in the normal elevation above the track, the gradients must be such that the current collectors on the locomotives and cars will follow the contact wire without leaving it, and without excessive pressure due to inertia; that is, the relative grades must not be too abrupt,

b. It must support without great distortion its own weight together with superimposed vertical loads due to sleet and horizontal loads due to wind,

c. It must possess consistency in flexibility; that is, hard spots should not occur in a construction designed to possess a certain amount of yielding, nor should soft spots occur in a system possessing inherent rigidity,

d. It must transmit the power supply, and afford suitable contact area with the moving collecting device on the locomotive or car, at the required speed,

e. It must possess a high degree of reliability, and ease of maintenance.

The problems of design are closely allied to transmission line design as far as power transmission problems and the choice of mechanical design of supporting structures are concerned. Some of the formulas developed for sags and stresses in transmission lines may be applied in a general way to the calculation of the contact system supporting messenger, although since this messenger is to support a conductor which is to be practically level without sharp departures from the horizontal, there will be certain limitations and refinements in the design not met with in the ordinary transmission line calculations.

Many features, such as insulation, suspension methods, bracing on curves and for wind loads, tensioning devices, anchorage details, and sectionalizing details are also involved in the design, although outside the scope of the main subject.

1. Assistant Electrical Engineer, N. Y., N. H., & H. Railroad.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

Part I. Tangent Construction

For a simple system where a working conductor is supported by an elastic messenger directly above it, the well-known parabolic equations will apply for all

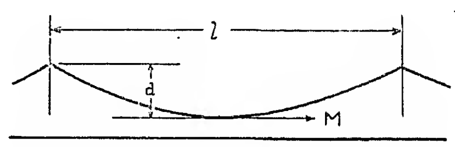

FIG. 1—SPAN, SAG, AND TENSION

span lengths generally encountered, since in general the sag is small compared with the span length.

In Fig. 1,

$$d = \frac{\gamma\, l^2}{8\, M} \qquad (1)$$

$$L = l + \frac{8}{3}\,\frac{d^2}{l} \qquad (2)$$

or

$$L = l + \frac{\gamma^2\, l^3}{24\, M^2} \qquad (3)$$

where

d is the deflection, or sag, of the messenger,
γ is the supported weight per unit length of span,
l is the distance between supports, span length,
L is the actual length of the messenger,
M is the horizontal component of the tension in the messenger.

The errors made in using these formulas, instead of the more unwieldy equations of the catenary, are approximately 2 per cent in the case of (1), and 0.5 per cent in the case of (2) and (3) for spans where the sag is not greater than 2 per cent or 3 per cent of the span length, which errors are well within construction allowances.

Sags according to (1) may be most conveniently shown graphically on logarithmic cross-section paper, as shown in Fig. 2.

Hanger Design

If the hanger spacing is s and the minimum allowable vertical distance between the contact and the messenger is v_0 then the length of any hanger is

$$v_n = d_n + v_0 \quad \text{(see Fig. 3)}$$

where d_n is the sag of the messenger for a span length of $2\,n\,s$

or

$$v_n = \frac{\gamma\,(2\,n\,s)^2}{8\,M} + v_0 \qquad (4)$$

Such hangers are called "standard" hangers, in distinction from "special" hangers, calculated from above formula when v_0 is replaced by any greater distance.

For a catenary system with horizontal contact wire, and with the same length shortest hanger at the low-point in adjacent spans, the distance from the low-point to the support is the same for spans both sides

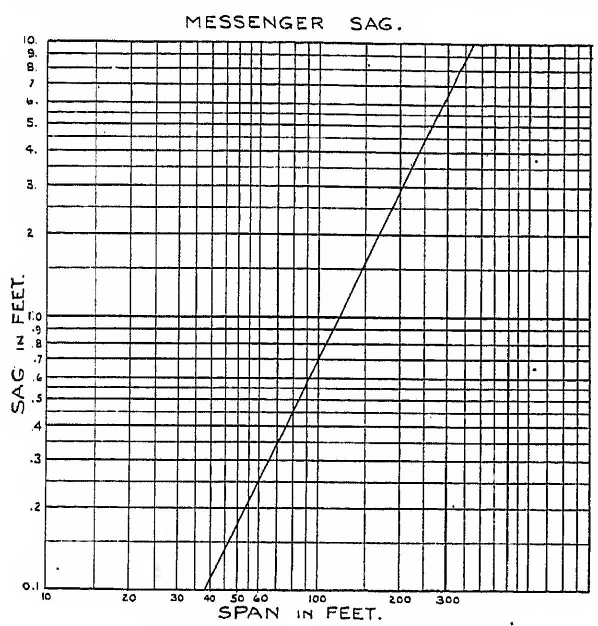

Fig. 2—Messenger Sag Curve

of the support, if the messenger tension and unit weight (γ) are the same in both spans; see Fig. 4.

The distance from low-point to low-point under these conditions has been called the "equipoise span" (l_E) since the weight either side of the support is the same; and the distance from the low-point to the support is designated the "equipoise half-span" $\frac{(l_E)}{2}$.

In Fig. 4, it is obvious that the weight supported by the structure is

$$W = \gamma\, l_E \qquad (5)$$

and the height of the supporting structure is

$$V = C + v_0 + d_E \pm I \qquad (6)$$

where

C is the height of contact wire above top of rail,

d_E is the sag for the equipoise span,

I is the height of the insulation, taken positive if of the suspension type, and negative if of the supporting type.

The formulas (5) and (6) are useful for the design of the supporting structures. It should be noted here that in calculating the horizontal loadings on the structures

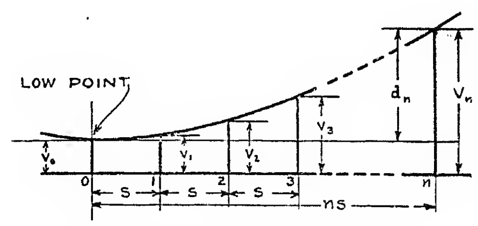

Fig. 3—"Standard" Hangers

due to wind, these will be the unit wind loading on the catenary multiplied by half the sum of the adjacent spans, which may or may not be the same as the equipoise span.

Spans having the same length of shortest hanger at the low-point will have the same hanger length at any given distance from the low-point. When the shortest hanger is "standard," all the other hangers in the equipoise span are standard, unless there is a change in grade in the contact wire.

If standard hangers can be used, the construction is greatly simplified, both as to cost of design, as well as manufacture and installation. Standard hangers will apply when the distances between supports are uniformly the same length, or when, if necessary to change the span length for any reason, length of any span is the sum of the lengths of each adjacent equipoise half-span. For example, if there is a series of, say, 300-ft.

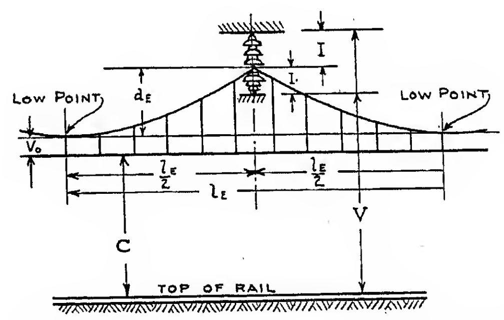

Fig. 4—Equipoise Span, and Height of Support

spans having standard hangers, and it becomes necessary to reduce the span length to, say, 200 ft. for several spans, to pass around a curve, if there is introduced between the last 300-ft. span and the first 200-ft. span a span having a length of 250 ft., then standard hangers can be applied to all the spans. Similarly, as in Fig. 5, successive span lengths of, say, 300, 250, 200, 150, 125, 200, 275, 300, may all have standard hangers, as each of these spans is the sum of the equipoise half-spans on either side. The equipoise spans for the above

would be: 300, 200, 200, 100, 150, 250, and 300, respectively.

This feature is worthy of emphasis, as a little extra study on the preliminary layout in location of supporting structures may save considerable calculations later if standard hangers are maintained.

Choice of Standard Maximum Span Length

Catenary construction presupposes much longer spans than direct suspension construction. The trend has been to make the spans as long as possible, having due regard for a practical and sensible choice of sags and

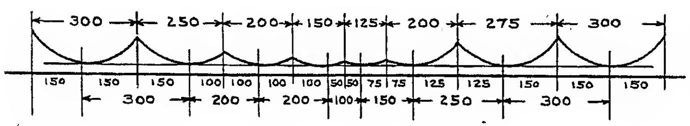

Fig. 5—Illustrating "Standard" Hanger Application and Equipoise Spans

tensions for the material used for the messenger. Three hundred feet has been more or less standardized for catenary construction on tangents, and has worked out fairly well in some cases. The writer is of the opinion that this length of span is a little too great for "single catenary" construction, especially in exposed places, on account of the large possible displacement due to wind; and the large possible variation in the height of

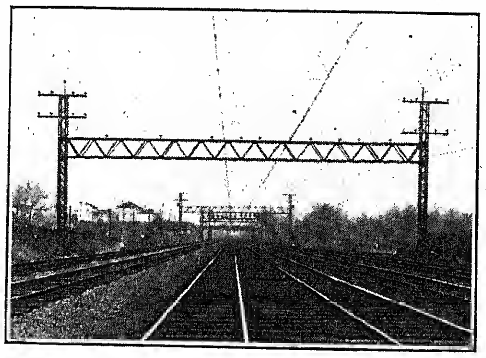

Fig. 6—Original "Woodlawn-Stamford" Type Double Catenary Installed in 1906 Over Four Hew Haven Main Tracks at Right, with New Single Catenary Installed 1925 Over Two "Westchester" Tracks at Left

contact at the center of the span due to temperature changes. Further, when the track alinement consists of a large amount of curvature, with short tangent stretches between, there is not always sufficient length on the tangents to make a material reduction in the number of supporting structures by going to such long spans and there is also the danger of having unbalanced stresses on the structures at extreme temperature conditions in going from very long spans on tangent to short spans on curves.

Wind bracing may be necessary on exposed tangent stretches having 300-ft. spans, especially on the types of construction which have no lateral stiffness against wind loads.

For the above reasons, 250 ft. was adopted as the standard maximum span length on tangent track on the Danbury Branch. On the extension of the New York, Westchester, and Boston to Harrison, which parallels the New Haven main line, use was made of the New Haven right of way and structures. This line is mostly tangent, and the existing catenary supporting structures are spaced 300 ft. apart.

Choice of Messenger Material and Sag

The "New Haven" has on its electrified system more than 650 track miles of catenary construction, embracing several types, all of which have been fully described to the Institute at various times. The original construction, installed in 1906 between Woodlawn, N. Y., and Stamford, Conn., is "double catenary," having two 9/16-in. extra high strength steel messenger strands,

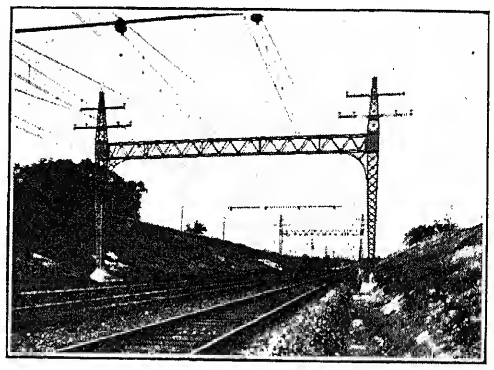

Fig. 7—Four-Track Compound Catenary on Tangent Between Stamford and New Haven, Installed 1913

each having a nominal vertical sag of 6 ft., 5 in. for a 300-ft. span; see Fig. 6.

The construction between Stamford and New Haven, and on the six-track Harlem River Branch, as well as on the four-track main line section of the N. Y., W., and B. Ry., is "compound catenary," with supports 300 ft. apart, from which main messengers, not alive, suspend the live single catenary. This has a normal span of 150 ft. The live catenary messengers are of extra high strength galvanized steel, 19-wire, ⅝-in.-diameter strand, having a sag which is equivalent to 5 ft., 0 in. in a 300-ft. span; see Fig. 7.

At certain points on this latter type of construction, the ⅝-in. messenger has suffered severe corrosion due to steam train traffic which is of necessity routed over part of the electrified zone. In replacing the steel messenger at these points with a high strength bronze strand, the factor of safety, which was five in the case of the steel strand to allow for the corrosion, could not economically be much greater than 2½, under assumed maximum loads, even though the messenger size were increased, on account of the increased weight. The lower factor of safety for bronze is allowable, because

of the low corrosion loss; but it was a fact to be kept in mind that this sag and tension was right at the limit for bronze, for the contact wire weight supported.

In 1921, the New York, Westchester, and Boston started extending its New Rochelle Branch parallel to the New Haven main line. As stated above, the New Haven had four tracks electrified in this section, but the catenary bridges were designed for six tracks. The new "Westchester" tracks were electrified, using single catenary construction supported on the same bridges which supported the New Haven double catenary. This new catenary had the same nominal sag, 6 ft., 5 in., as the old double catenary for the 300-ft. spans, and a single 9/16-in. extra high strength steel messenger strand, galvanized, was used.

Steel was used because there is no steam traffic of any nature on this line, but the characteristics of this

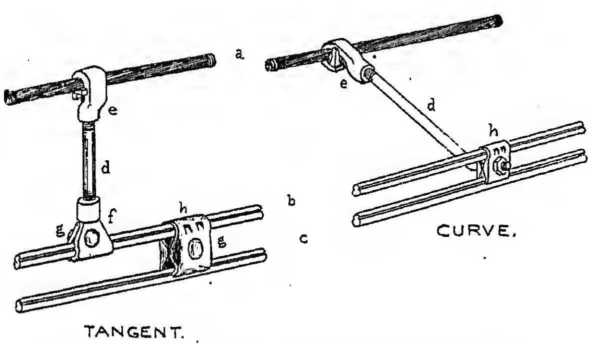

FIG. 8—CATENARY CONSTRUCTION DETAILS

a. 9/16-in. steel Messenger strand
b. 4/0 copper auxiliary trolley
c. 4/0 Phono contact wire
d. ½-in. steel hanger rod
e. Malleable iron messenger hook
f. Malleable iron auxiliary trolley clip
g. ½-in. steel carriage bolt
h. Pressed phono intermediate clip

design are such that because of the larger sag, bronze can be economically substituted if the occasion ever warrants.

This same design was selected, for these reasons, for the Danbury Branch.

Deterioration due to corrosion has an important bearing on the choice of messenger material. If steam traffic can be entirely eliminated by electrification, steel may be economically used with an expectancy of reasonably long life, if properly maintained by painting. Much of the original 9/16-in. messenger installed on the Woodlawn-Stamford section of the New Haven over 20 years ago, is in very good condition at the present time on this account. Maintenance of this kind on busy traffic routes is both difficult and expensive, however, and where the traffic is dense, therefore, the higher first cost of non-ferrous materials such as bronze, is justified on new work.

As against the excellent record of the Woodlawn-Stamford messenger, mention must be made of the steel messenger construction installed in 1912 in the large freight yards of the New York tidewater terminals, which have recently been entirely reconstructed with bronze messengers and hanger rods. The combination of the heavy salt fogs, with more or less steam traffic, produced conditions which were unusually severe.

On the Danbury Branch, however, because of the low traffic density, the practical elimination of steam operation, and the drier atmospheric conditions away from the salt water, it was felt that the higher cost of bronze was not justifiable.

The complete characteristics of this type of catenary are as follows: see Fig. 8

Messenger: 9/16-in.-diameter, 7-wire extra high strength steel strand, extra heavily galvanized.

Sag: 6 ft., 5 in. in 300-ft. span, with normal load at 60 deg. fahr.

Auxiliary trolley: 4/0 grooved hard drawn copper.

Contact wire: 4/0 grooved Phono bronze, 45 per cent conductivity.

Hanger rods: ½-in. round galvanized steel rods.

Hanger hardware: Malleable iron castings, heavily galvanized.

Intermediate clips: (Aux. to contact) pressed Phono bronze.

UNIT LOADINGS

(Pounds per Foot)

Material	Vertical (Bare)	Vertical (½-in. Sleet)	Horizontal (Wind on Sleet)	Resultant (Wind and Sleet)
9/16-in. Mess..........	0.668	1.329	1.042	1.69
4/0 Copper............	0.641	1.241	0.973	1.575
4/0 Phono.............	0.641	1.241	0.973	1.575
Hangers and Clips......	0.273	0.465	0.272	0.54
Total...............	2.223	4.276	3.260	5.380

NORMAL TENSIONS

At 60 deg. fahr.

9/16-in. Messenger... 3900 lb. (from equation (1))
4/0 Copper......... 1600 lb. (from Fig. 9.)
4/0 Phono.......... 1815 lb. (from Fig. 9.)

The tensions in the copper and the phono were determined as follows:

The change (ΔL) in a given length (L) of any material having a coefficient of linear expansion (α) due to a change (Δt) in temperature, is

$$\Delta L = - L \alpha \Delta t \tag{7}$$

The change (ΔL) in a given length (L) of material having a modulus of elasticity (E), due to its elasticity, for a change in tension (ΔT) is

$$\Delta L = \frac{L \Delta T}{E a} \tag{8}$$

where a is the cross-sectional area.

If the change in tension is all due to a change of temperature, (7) will be equal to (8).

Then

$$- L \alpha \Delta T = \frac{L \Delta T}{E a}$$

or

$$\Delta T = - a E \alpha \Delta T \quad (9)$$

For copper

α = 0.0000094 per deg. fahr.

E = 17,500,000 lb. per sq. in., solid wire.

For Phono

α = 0.0000093 per deg. fahr.

E = 18,140,000 lb. per sq. in., solid wire.

For 4/0

a = 0.1662 sq. in.

Substituting the above values in (**9**), and plotting for various values of t, and assuming a minimum of 100-lb. tension in the contact wire at the maximum assumed temperature (+ 120 deg. fahr.) gives the values shown in Fig. 9. It will be noted that these tensions are kept as low as possible on the theory that horizontal loads on the supporting structures on curves are thereby reduced to a minimum, and the maximum flexibility is provided for the contact wire. Although the curve of auxiliary wire tensions is shown as zero at the maximum temperature, it will always have some tension due to the weight of the contact wire which it supports.

Maximum Tensions

The maximum stress in the messenger and trolley wires must be determined in order to insure that the material and sizes selected will have ample strength to withstand the maximum loads to be experienced. The maximum loading is assumed to be eight lb. of wind pressure on the projected area of all material when covered with a coating of sleet one-half-inch thick.

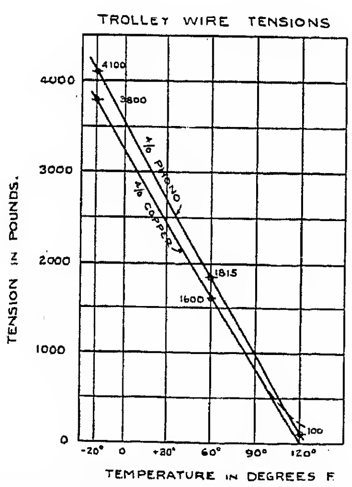

Fig. 9—Temperature-Stress Diagram for Auxiliary and Contact Wires

The maximum stress in the auxiliary and the contact wires is readily found from Fig. 9. The messenger stresses are determined as follows:

From equation (3), for a given span length (l), the actual length (L) of the messenger may be plotted for various values of tensions (M) and unit loadings (γ); see Fig. 10.

γ_1 is for the bare messenger alone (0.668 lb.)

γ_2 is for the messenger with the two trolley wires but without hangers (1.95 lb.)

γ_3 is for the complete catenary, without wind or sleet loads (2.22 lb.)

γ_4 is for the complete catenary with wind and sleet loads included (5.38 lb.)

Point A on the normal load curve may be taken to represent the messenger length and tension at 60 deg. fahr., normal temperature.

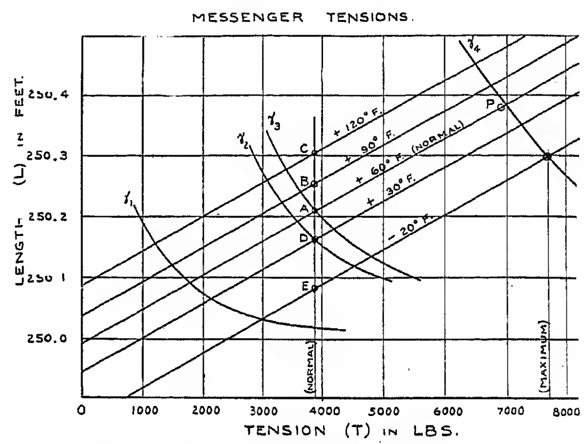

Fig. 10—Temperature-Stress Diagram for 9/16-in. Steel Messenger

From equation (**8**) may be calculated the amount the messenger would stretch for any increase in tension (assuming constant temperature), plotting this new length and tension at P.

For 9/16-in. steel strand,

a = 0.1992 sq. in.

E = 23,000,000 lb. per sq. in.

α = 0.0000064 per deg. fahr.

A straight line drawn through A and P will give any value of L for any value of T with constant temperature of 60 deg. fahr.

For any constant tension, the change in length due to a change in temperature may be found from equation (7), and points B, C, D, and E, using lengths as at A may be found thus for 90 deg., 120 deg., 30 deg., and − 20 deg. fahr., respectively. Lines through these points drawn parallel to $A P$ will indicate the variation in length due to a change in tension for that temperature.

The maximum stresses determined thus are:

9/16-in. Messenger . . 7700 lb.		
4/0 Copper . . . . 3800 lb.	}	at − 20 deg. fahr.
4/0 Phono . . . . 4100 lb.		

The tensions at which the bare messenger may be installed alone at various temperature conditions may be found from the intersections of the lines A, B, C, D,

and E with the curve γ_1. If the stress is to be determined by the sag of the messenger, a curve may be made similar to Fig. 11, showing no-load sags for various spans and temperatures. Similar graphical data may be made for the sagging of the messenger with the load of the two trolley wires, but without the hangers, as is desirable in certain instances when these are all strung out together.

Fig. 12 shows the details of the tangent construction used on the Danbury Branch. The poles are 10-in., 49.5-lb. Bethlehem H sections, either 36 or 38 ft. in length. These are self-supporting, being bolted to the foundation channels with a sufficient number of one-in. bolts to develop the full strength of the section. Bracket arms are adjustable as to height, and are attached to the flanges of the poles by malleable iron clamp castings. This is a valuable feature of the design,

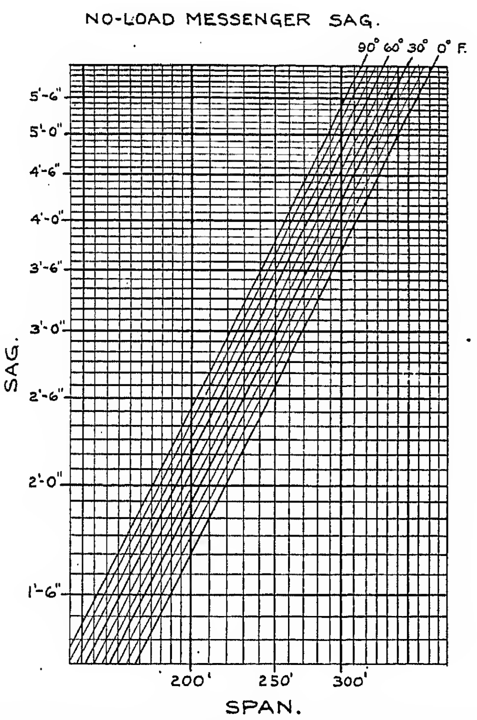

Fig. 11—No-Load Sags for 9/16-in. Messenger for Various Temperatures

as it is not necessary to specifically mark each pole for each location; fabrication is reduced; and if it ever becomes necessary to raise the grade of the track (by ballasting), or to change the number or dimensions of insulator units, these may be done without reducing the standard contact wire height, by raising the brackets, without additional work on the poles.

Fig. 13 shows graphically the proper pole length and the bracket height for this type of construction, for various equipoise half-spans, calculated from formula (**6**) above.

Suspension insulators, consisting of three units, were used, instead of the pin type supporting the messenger above the bracket arm, used in previous installations, as the suspension type allows a greater insulation value, and takes care of the possibility of unbalanced stresses better. This makes a system having a greater possibility of deflection to transverse wind loads, and it

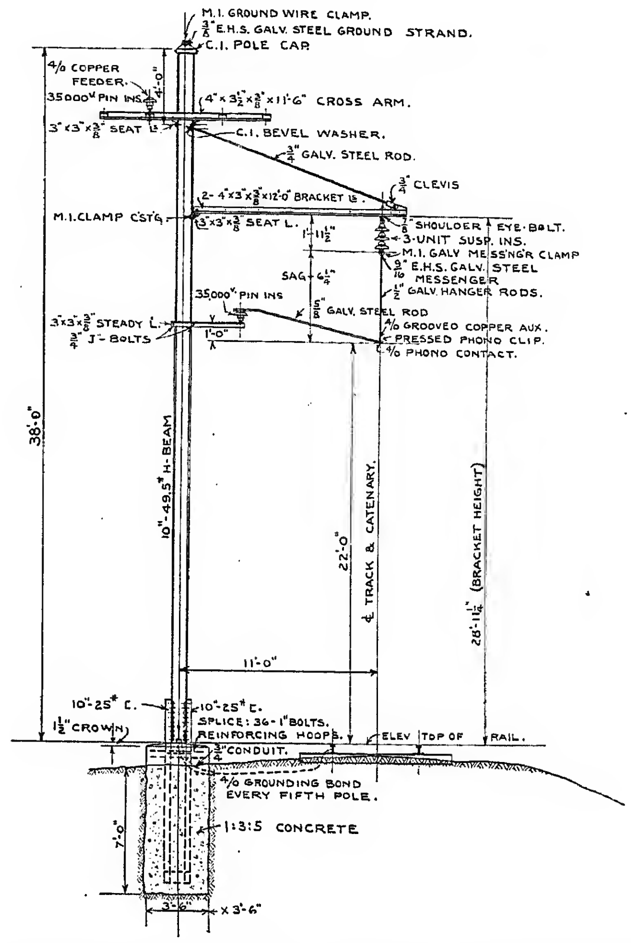

Fig. 12—Standard Tangent Bracket Pole for 250-Ft. Span

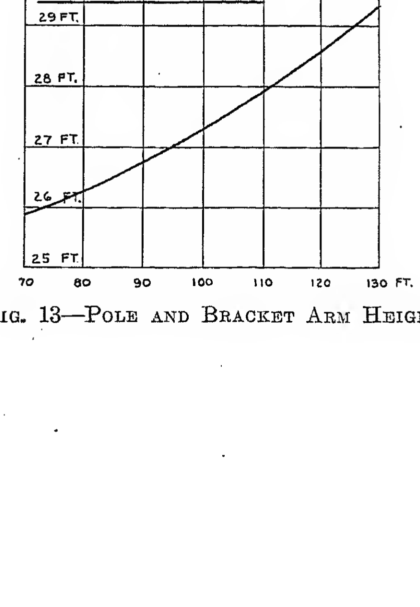

Fig. 13—Pole and Bracket Arm Heights

therefore seemed desirable to provide a steady rod or wind brace between the contact wire and the pole. This, with all other details, is shown in Fig. 14, which illustrates the finished appearance of the tangent construction on the Danbury Branch.

On the New York, Westchester, and Boston extension, pin type supporting insulators were necessarily used on account of the height of the existing structures that were used. No wind bracing has as yet been found necessary on this line, as it is somewhat shielded.

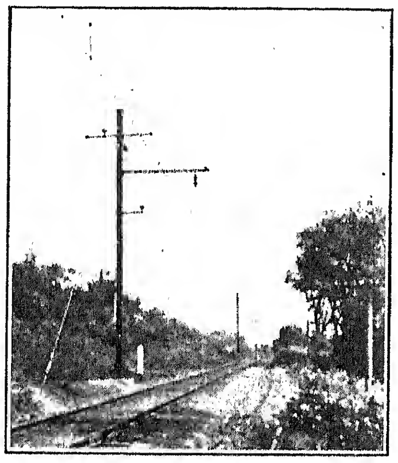

FIG. 14—TANGENT SINGLE CATENARY CONSTRUCTION ON DANBURY BRANCH. INSTALLED 1925

Part II. Catenary Construction on Curves

A. TANGENT-CHORD CONSTRUCTION

Tangent construction, suitably deflected, may be carried around any curve in a series of chords, with spans equal to the chords, or equal to the sum of several chords, using intermediate pull-off poles. Poles are preferably located on the outside of the curves.

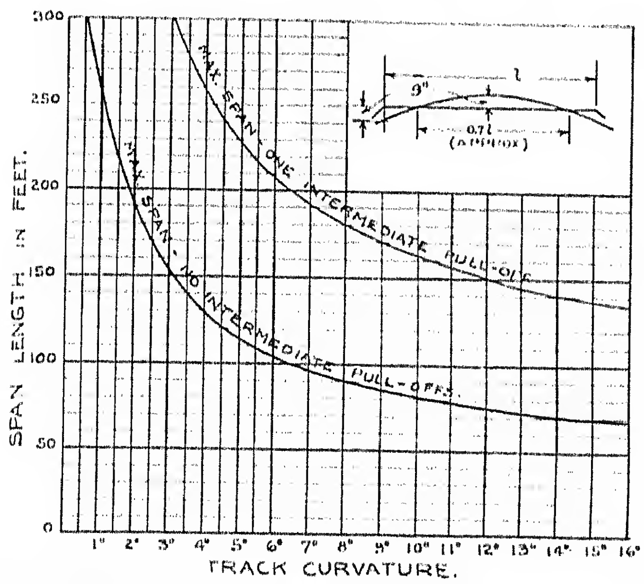

FIG. 15—MAXIMUM SPAN LENGTHS—TANGENT-CHORD CONSTRUCTION ON CIRCULAR CURVES

The length of these chords will depend upon the degree of curvature and the maximum allowable departure (q) of the contact wire from the centerline of the pantograph collector. With a pantograph similar to that used on the New Haven equipment, the maximum allowable departure for design purposes is nine in. either side of the centerline. This means that a chord making a middle ordinate of 18 in. on any curve, is the maximum length of tangent catenary which can be used on that curve. Fig. 15 shows in graphic form the maximum chord length for tangent-chord construction, together with maximum span length for no intermediate pull-off poles, and for one intermediate pull-off pole, for a maximum middle ordinate of 1.5 ft., for various degrees of curvature. The contact wire is not, strictly speaking, a chord, but a secant to the curve, parallel to, and of the same length as, the chord, and distant from it an amount equal to half the middle ordinate, or nine in., (q). An interesting relationship, which is of value, is that this secant crosses the curve at points which are approximately 15 per cent of the chord length distant from the pull-off points, for all curves used in railroad work.

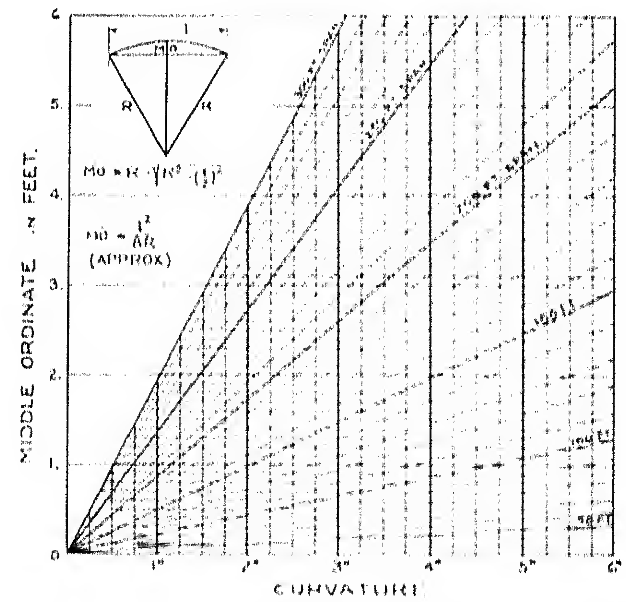

FIG. 16—MIDDLE ORDINATE CHART FOR VARIOUS SPANS AND DEGREES OF TRACK CURVATURE

The middle ordinate, MO, for any curve and chord is found from the expression

$$MO = R - \sqrt{R^2 - \left(\frac{l}{2}\right)^2} \qquad (10)$$

where R is the radius of the curve, and l is the chord length.

A convenient graphical representation is shown in Fig. 16. On curves and spans usually encountered in railroad work, the following parabolic expression may be substituted for (10):

$$\overline{MO} = \frac{l^2}{8\,R} \qquad (11)$$

which is more convenient, and accurate to within 0.5 per cent.

Since

$$R = \frac{5730 \text{ ft.}}{D} \quad \text{(approximately)} \qquad (12)$$

where D is the curvature in degrees, this may be written

$$\overline{MO} = 0.0000218\, l^2\, D \qquad (13)$$

for all ordinary spans and curves.

In going from tangent to a curve, it is obvious that the limit to which the tangent can be extended beyond the point of curvature before a deflection becomes necessary, is where the "tangent offset" to the curve is equal to the allowable departure (q) from the centerline

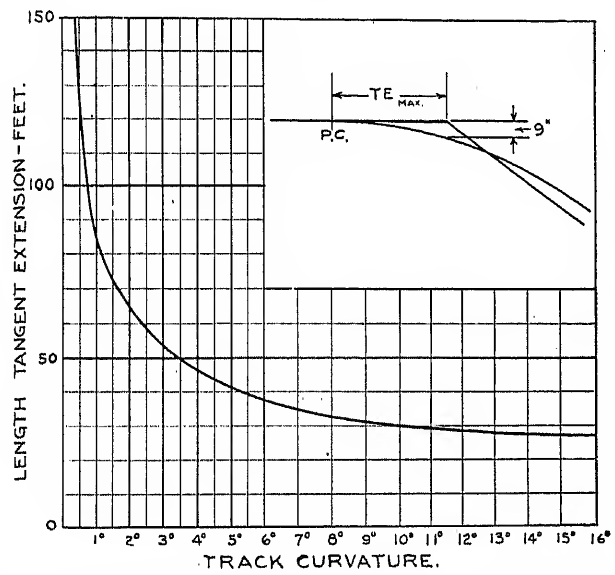

Fig. 17—Maximum Tangent-Extension for Tangent-Chord Construction for Various Degrees of Curvature

of the pantograph. In other words, the distance from the point of curvature to the first pull-off must not be greater than one-half of the chord whose $\overline{MO}$ is equal to q.

Fig. 17 shows this relationship, and gives a curve of "maximum tangent extensions" for various degrees of curvature, for q equal to 9 in.

On symmetrical reverse curves (having no tangent between) as on cross-overs and turnouts, or where main track is sometimes deflected for "island" station platforms, the wire must obviously be over the point of reverse curvature and should be secant to both curves so that all four maximum departures from the curves are equal; see Fig. 18.

It may be shown that the wire will cross the curve at points which are approximately 1/12 of the span length from the ends of the span, under these conditions. Fig. 18 also gives the maximum span which can be used on various degrees of reverse curvature, when q is equal to 9 in.

On tangent-chord construction, the contact wire will be offset from the pantograph centerline towards the outside of the curve an amount equal to q. The track, however, has the outside rail elevated above the level

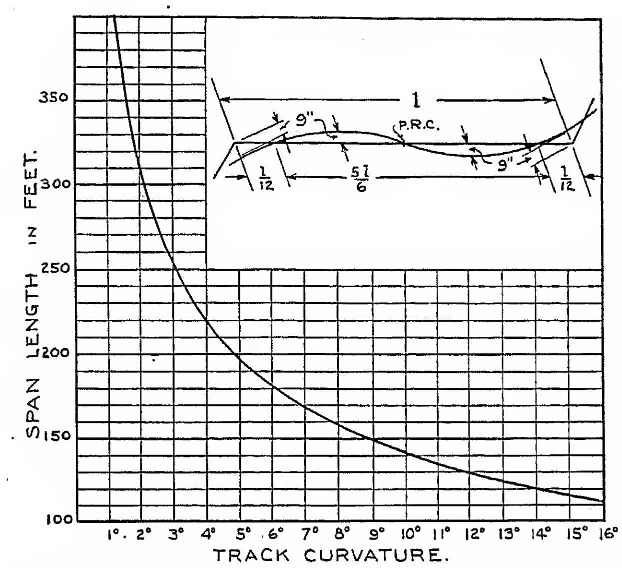

Fig. 18—Maximum Span Length for Tangent-Chord Construction on Reverse Curves of Various Degrees of Curvature

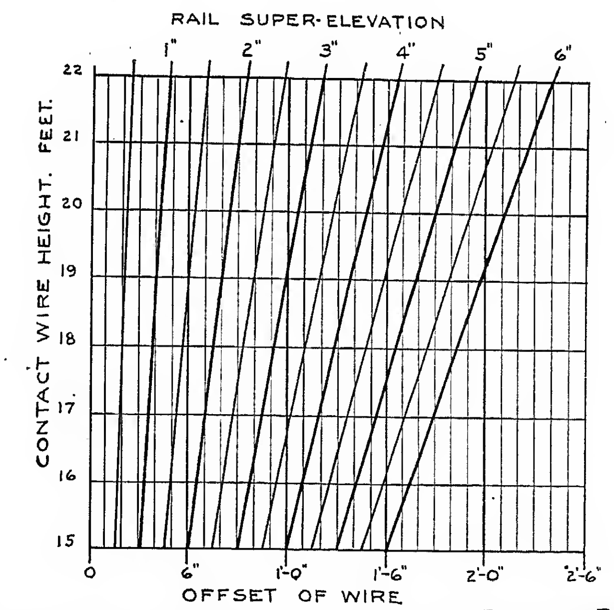

Fig. 19—Contact Wire Offset for Various Values of Rail Super-Elevation and Contact Wire Heights

of the inside rail, which will tilt the centerline of the locomotive and pantograph towards the inside of the curve an amount proportional to the super-elevation of the outer rail and the contact wire height.

Fig. 19 shows the offset z of the pantograph centerline from the track centerline, due to rail super-elevation, for

various values of trolley height and super-elevation.

It is apparent that the true offset 0 of the insulator (and wire) from the track centerline, which is the base line for all construction measurements, will be

$$O = q - z \tag{14}$$

When O is positive, the wire is located outside the track centerline curve.

When O is negative, the wire is located inside the track centerline curve.

Fig. 20 shows diagrammatically this relationship, and a typical design of tangent-chord bracket construction on curves.

If no intermediate pull-off poles are used, the horizontal forces on the catenary supports due to the deflection of the messenger and the contact wires will be:

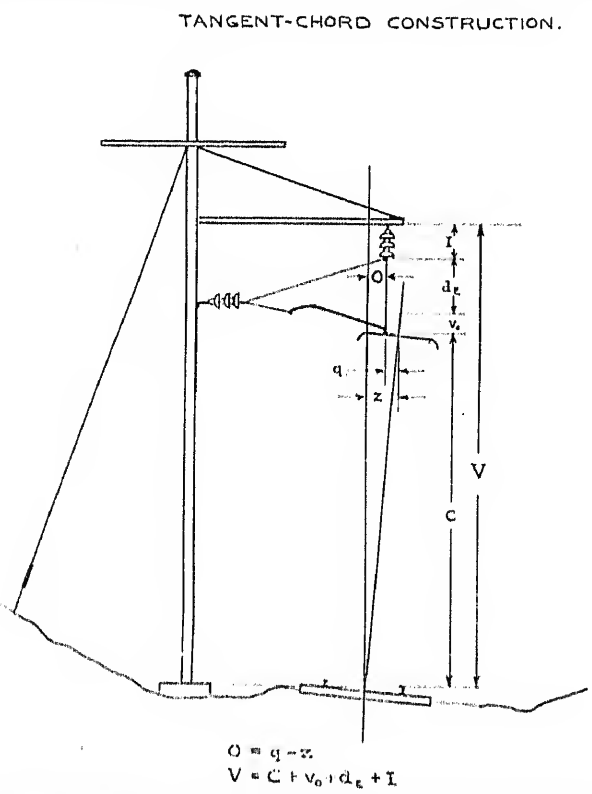

FIG. 20 ILLUSTRATING BRACKET-ARM AND INSULATOR OFFSET ON TANGENT-CHORD CONSTRUCTION

For the messenger,

$$P_M = \frac{l\,M}{R} \tag{15}$$

For the trolley, or auxiliary and contact,

$$P_T = \frac{l\,T}{R} \tag{16}$$

where P_T is the "curve-pull" in pounds and T is the sum of the tensions in the auxiliary and the contact wires.

The total curve pull on the structure will be

$$P = \frac{l\,(T + M)}{R} \tag{17}$$

in addition to wind loads. If intermediate pull-offs are used, l will be reduced to an amount equal to the chord length.

Tangent-chord construction has certain distinct advantages. The design details are the same on curves as on tangents, and the alinement of the wire is practically fixed, so far as temperature changes and wind loads are concerned. This type of construction is recommended for track alinements having a small proportion of curvature, or where the curves are short, and heavy; or where, as in yard or siding work, many switches and turnouts are encountered. This type of construction was used on the short curves at the station approaches on the New York, Westchester, and Boston extension, of which Fig. 21 is an illustration.

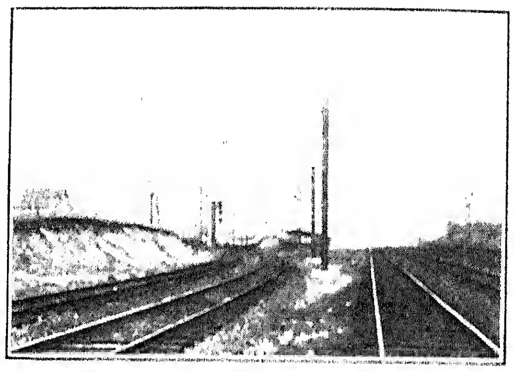

FIG. 21 TANGENT-CHORD SINGLE CATENARY CONSTRUCTION ON EIGHT-DEG. REVERSE CURVE AT STATION APPROACH, N. Y. B. & W. RY. 1925

B. INCLINED CATENARY CONSTRUCTION

A study of the curve shown in Fig. 15 shows that the pole spacing with tangent-chord construction decreases very rapidly for curves up to about five deg., and at a slower rate for curves above five deg. This means more supports, each with double the usual number of insulators required for tangent construction, on account of the pulloffs; which of course increase the cost.

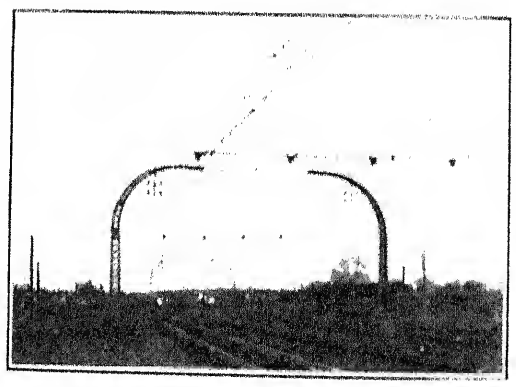

FIG. 22 THE ORIGINAL "INCLINED CATENARY" INSTALLATION. EXPERIMENTAL COMPOUND CATENARY CONSTRUCTION AT GLENBROOK, 1909

In 1909, the New Haven engineers developed the so-called "curved catenary," or what is more commonly

now called "inclined catenary" (on account of the position assumed by the hangers) with the idea of eliminating to a large extent the necessity of pull-offs, and also increasing the span length, on curves of moderate degree of curvature.

The original installation was an experimental stretch of four-track construction one mile in length at the easterly end of the original double catenary construction, near Glenbrook, Conn.; see Fig. 22. This was compound catenary, with 300-ft. spans on both tangent and two-deg. curve. The live single catenary consisting of a ⅝-in. steel strand with a 4/0 copper auxiliary and 4/0 contact wire was supported from two main messengers, not alive, every 100 ft. Over the curved track, the contact wire followed the track alinement very closely, and the hangers were inclined at an angle which was the resultant of the weight of the trolley wires and the curve-pull reaction between these wires and the messenger.

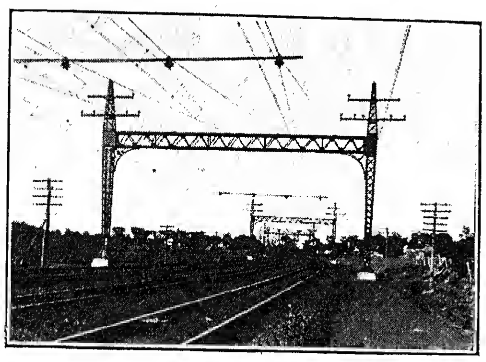

FIG. 23—COMPOUND CATENARY CONSTRUCTION INSTALLED IN 1913 BETWEEN STAMFORD AND NEW HAVEN, SHOWING INCLINED CATENARY ON TWO-DEG. CURVE

This type of construction seemed to present such distinct advantages over the double catenary, that it was adopted, in a form modified as to supporting structures and main messenger construction, for the electrification of the six-track Harlem River Branch, and the four-track New York, Westchester, and Boston, in 1911, and for the four-track extension to New Haven in 1913, which is shown in Fig. 23. The design of this type of construction has been very completely described by Mr. Sidney Withington, in the *Journal of the Franklin Institute*, December, 1914, Vol. CLXXVIII, No. 6.

On this type of compound catenary, the live catenary spans were fairly short, being but 150 ft. for the maximum condition. The calculation involving the inclined rods on curves was therefore comparatively simple, as the errors made in assuming the hangers had the same inclination throughout the span, were very small. These calculations were based on the theory that the contact wire had a parabolic shape, with the horizontal "sag" equal in value to the middle ordinate of the circular curve of the track for that span. The horizontal force or "curve-pull" was assumed to be uniform for each hanger rod. Both of these assumptions are fallacious, but do not introduce appreciable errors until it is attempted to apply this method of design to single catenary having much longer spans, and on sharper curves.

The following solution of this problem is not new; some of it is not original; but it has not, to the writer's knowledge, been set forth heretofore in a form which is available for engineers who may be interested in the general problem of catenary design.

The fundamental characteristics of the inclined catenary may be summarized as follows:

1. The projection of this type of construction on a vertical plane passing through the points of support is the same as for standard tangent construction, and the contact wire is a horizontal straight line.

2. When projected on a horizontal plane, the contact wire, instead of being a straight line as in tangent-chord construction, is a curve which is intended to approximate the track alinement curve. The messenger also appears as a curve, similar to, but not necessarily of same degree as, the shape of the contact wire, and curved in the opposite direction; see Fig. 24.

The problem is to combine these characteristics and to find the length of any hanger under various conditions of span length and track curvature. Before undertaking the solution, the factors entering into the problem must be resolved into their simplest forms. It is apparent that two opposing systems in static equilibrium are being dealt with and that some of the factors involved are the weights and tensions in each system. Therefore if either or both of the systems be composed of more than one element, the elements must be combined and replaced, for calculation purposes at least, by a single element whose tension and weight has the same effect on each system as the elements thus replaced.

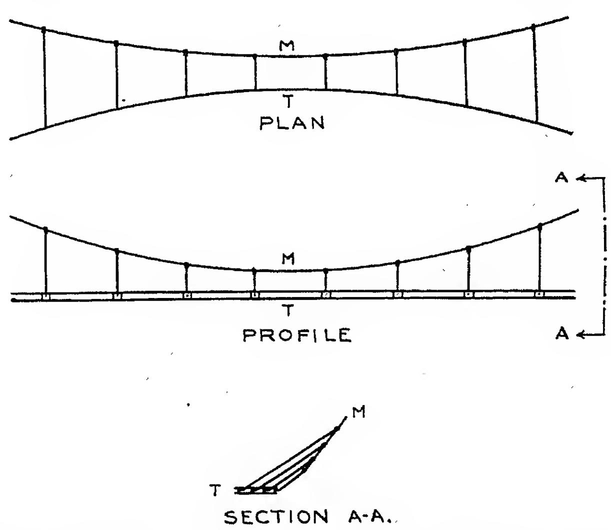

FIG. 24—INCLINED CATENARY. GENERAL CHARACTERISTICS

The design used on the Danbury Branch, described

in Part I, will be used to illustrate the theory throughout this discussion, although the general theory will apply to any other design. In the solution of this particular design, the two 4/0 wires must be replaced by a single element having a tension equal to the sum of the normal tensions in these two wires. Their weight must also be combined, and with it should be included the weight of the hardware used on the lower end of the rods, together with one-half of the weight of the rods themselves. This may be designated the

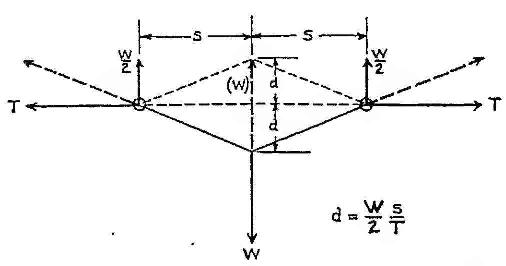

Fig. 25—Illustrating Relation of Displacement to Stresses in a Simple Symmetrical System

"trolley system." To the messenger must be added the weight of the hardware on the upper end of the rods, as well as the other half of the weights of the rods. This is the "messenger system."

The combined characteristics then are, for normal conditions:

	Tension	Unit weight
Messenger System..........	3900 Lb.	0.732 Lb. (Min.)
Trolley System............	3415 Lb.	1.336 Lb. (Min.)

Since, in this type of construction, the rods may be-

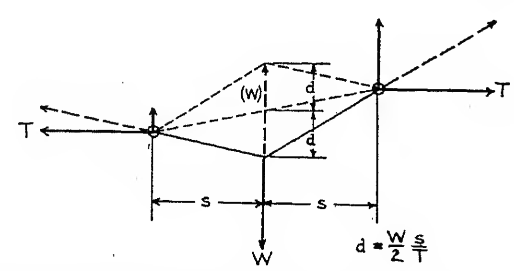

Fig. 26—Illustrating Relation of Displacement to Stresses in a Simple Asymmetrical System

come quite long, it will make for closer accuracy to assume that the unit weight of each system is to be compensated for the increase in hanger weight from the center to the ends of the span. Therefore, the weights given above are based on short hanger lengths at the center of the span.

Relation Between Messenger and Trolley Curve. In Fig. 25, let W be a weight suspended from a flexible weightless strand at a point midway between two fixed supports which are on the same level, and at a distance $2\,s$ from each other.

Let d be the deflection or sag in the strand;

Let T be the horizontal component of the tension in the strand.

Then, by construction,

$$d : s :: \frac{W}{2} : T$$

or

$$d = \frac{W}{2}\,\frac{s}{T}$$

This relationship holds true even if the points of suspension are not on the same level, provided s and T are always taken horizontal (or perpendicular to W) and parallel, as may be seen from a study of Fig. 26, since, by construction,

$$2\,d : W :: s : T$$

or

$$d = \frac{W}{2}\,\frac{s}{T}$$

It is apparent that the above relationship will also

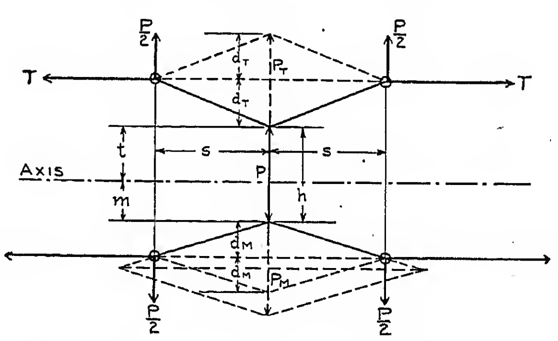

Fig. 27—Two Simple Combined Opposing Systems. Illustrating Relation of Displacements to Tensions

apply to forces acting in a horizontal plane, where the weight W is replaced by a horizontal pull P; and the strand will indeed be "weightless" under these conditions.

The above expression will then become

$$d = \frac{P}{2}\,\frac{s}{T} \tag{18}$$

In a horizontal system just described, the pull P may be produced by a connection to another similar system having the same distance ($2\,s$) between its supports and an equal but opposite force P. The tension in the strands of each system may be the same, or they may be different, in which case the deflections will be different; for, in Fig. 27, let system 1 have a horizontal tension T in its strand, with a deflection d_T due to the pull P.

From (**18**):

$$d_T = \frac{P\,s}{2\,T}$$

Let System 2 have a horizontal tension M in its strand, with a deflection d_M due to the same pull P.

Then

$$d_M = \frac{P\,s}{2\,M}$$

and

$$2\,T\,d_T = P\,s = 2\,M\,d_M$$

whence

$$\frac{d_M}{d_T} = \frac{T}{M} \tag{19}$$

If, in Fig. 27, the distance between the systems at the tie through which P acts, is h, this length may be divided into two parts, t and m

$$h = t + m \tag{20}$$

such that

$$m : t :: d_M : d_T \text{ or } \frac{m}{t} = \frac{d_M}{d_T}$$

Substituting in (**19**),

$$\frac{m}{t} = \frac{T}{M} \tag{21}$$

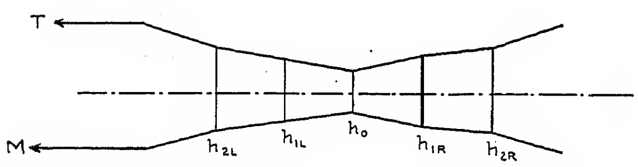

Fig. 28—Mutual Reflection of Shape in Two Opposing Systems

then

$$m = t\,\frac{T}{M}$$

Substituting in (**20**),

$$h = t\left(1 + \frac{T}{M}\right) \tag{22}$$

If the two systems are balanced against each other by ties at regular intervals (s), it is apparent from the foregoing that the deflection in either system due to the pull at any tie, referred to its two adjacent tie points, will have the definite relationship expressed by (**19**), and that any tie can be divided into two parts which will have the relationship expressed by (**21**). It follows that a line drawn through each of these division points on every tie is a straight line perpendicular to each tie, since by construction the ties are all parallel. This line may be called the system axis.

The ties may be such that each system has an irregular shape as in Fig. 28, in which case some ties may have no tension (as h_{1L} in the figure), or some may have compression (as h_{1R} in the figure); or the ties may be so designed that the systems have a symmetrical shape about an axis through the shortest tie, perpendicular to the system axis, as shown in Fig. 29. A symmetrical system may be tangent to the other symmetrical system at the shortest tie, when this is equal to zero, or the two systems may even be crossed and reversed, as shown in Fig. 30.

In each and every case, the following relations obtain:

$$h = t + m \text{ for any tie.}$$

$$H = H_T + H_M$$

$$\frac{m}{t} = \frac{d_M}{d_T} = \frac{T}{M} = \frac{H_M}{H_T}$$

The general statement may therefore be made that

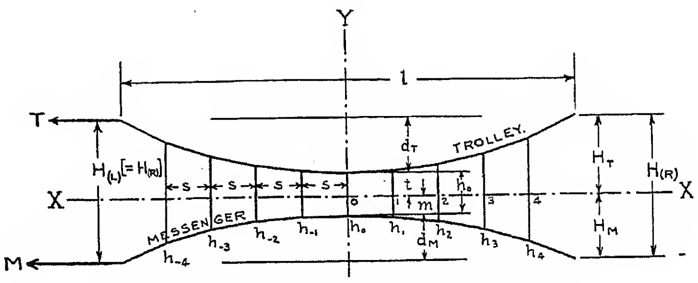

Fig. 29—Inclined Catenary Construction

Two combined opposing systems with symmetrical horizontal displacements about axis through shortest tie. (The *U*-shape.)

the shape of the trolley system, referred to the system axis, will be a reflection of the shape of the messenger system, and vice versa; differing only in degree, which degree is expressed by the inverse ratio of their respective tensions.

It is apparent from an inspection of the two symmetrical curves shown in Figs. 29 and 30, that they are both some function of the span length. If the system axis is represented by the X axis, and the perpendicular axis through the shortest tie is represented by the Y axis, then either of these curves may be expressed

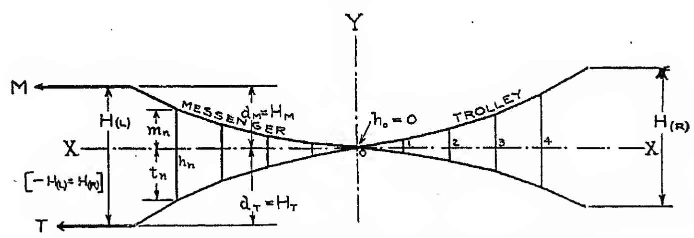

Fig. 30—Inclined Catenary Construction

Two combined opposing systems which are crossed and reversed, having similar horizontal displacements about axis through shortest tie. (The *S*-shape.)

$$y = f\,(x)$$

Before these symmetrical shapes can be applied to the track curve, something of their nature must be known to determine their adaptibility and their limitations. One method of doing this would be to plot their shapes, as determined by use of their correct constants, for comparison with the shape of the track curve.

Track curves are, in general, circular, but the equation of the circle, and especially that of circular middle ordinates, (**10**), is rather unwieldly. If it can be assumed that the track curve is a parabola, the parabolic expression (**11**) for the middle ordinate is much more conveniently handled. The middle ordinate of a 300-ft. span on a four-deg. curve when calculated by (**10**) is 7.80 ft. and when calculated by (**11**) is 7.85 ft. The difference or error is only five parts in 780, or 0.64 per cent. As this is an extreme case, it is apparent that for the spans and curves involved, it is well within the allowable limits to assume that the track curve is a parabola instead of a circle.

The general expression for the parabola is

$$a\,y = b\,x^2 + c$$

This may also be written

$$y = A\,(b\,x^2 + c) \text{ or } y = A\,f\,(x) \qquad (\mathbf{23})$$

where $(b\,x^2 + c)$ is a function of x which determines

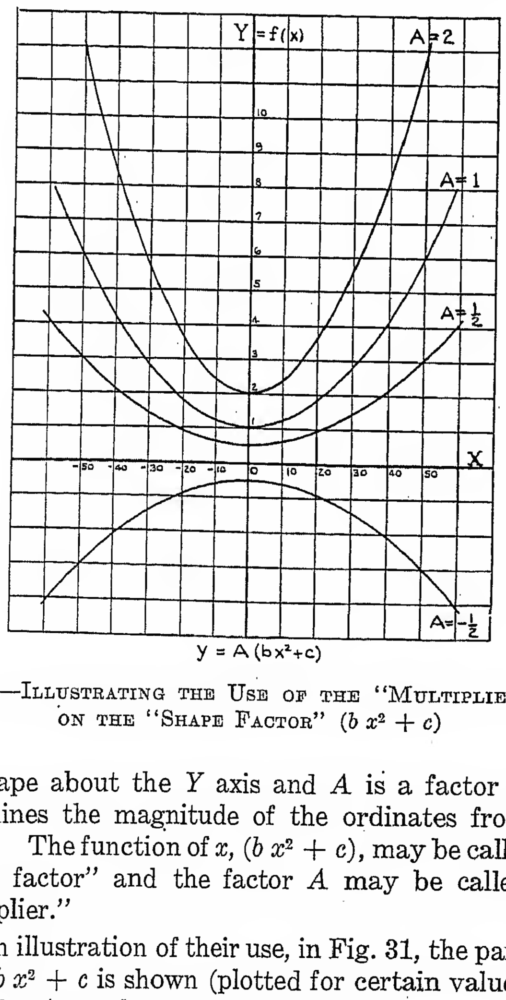

Fig. 31—Illustrating the Use of the "Multiplier" (A) on the "Shape Factor" $(b\,x^2 + c)$

the shape about the Y axis and A is a factor which determines the magnitude of the ordinates from the X axis. The function of x, $(b\,x^2 + c)$, may be called the "shape factor" and the factor A may be called the "multiplier."

As an illustration of their use, in Fig. 31, the parabola $a\,y = b\,x^2 + c$ is shown (plotted for certain values of b and c) for A equal to 1, 2, ½, and − ½.

The shape in each case is the same, (parabola), and each curve has the same constants for b and c for a given value of x; but the curve where $A = 2$ has ordinates twice those of the curve $A = 1$, and similarly the latter curve has ordinates twice the value of those of the curve $A = ½$. The ordinates of the curve $A = -½$ are equal to those of the curve $A = ½$, but are on the opposite side of the X axis. If the ordinates of the two last mentioned curves are combined, and added geometrically, their result will be a new curve having the same "shape factor," but a new value of A, in this case, equal to 1.

Curve $A = 1$ has the following value of $f\,(x)$ for different values of x

$\pm x$	$f\,(x)$
0	1.0
10	1.2
20	1.8
30	2.8
40	4.2
50	6.0
etc.	etc.

Each of these ordinates, multiplied by any value of the "multiplier" A, will always give a curve having the same "shape factor" $f\,(x)$.

In Fig. 29, which is that of two symmetrically opposed horizontal systems, let the curve of the trolley system be

$$y = A_T\,F\,(x) \text{ and let } F\,(x) = U$$

The Y axis corresponds to the axis of horizontal displacements, H.

Whence

$$H_T = A_T\,U \qquad \text{for the trolley}$$

and

$$H_M = A_M\,U \qquad \text{for the messenger}$$

Then the distance between the trolley and the messenger is

$$H = A\,U \qquad (\mathbf{24})$$

where

$$A = A_T + A_M$$

and the multiplier A and the shape factor U are to be determined.

Similarly, in Fig. 30, which is also that of two symmetrically opposed systems, but which are crossed and reversed, let the curve of the trolley be

$$y = B_T\,F'\,(x) \text{ and let } F'\,(x) = S$$

Then, as above,

$$H_T = B_T\,S \qquad \text{for the trolley}$$

and

$$H_M = B_M\,S \qquad \text{for the messenger}$$

and the distance between the trolley and the messenger is

$$H = B\,S \qquad (\mathbf{25})$$

where

$$B = B_T + B_M$$

and the multiplier B and the shape factor S are to be determined.

In the symmetrical system shown in Fig. 29,

$$H_R = H_L = A\,U$$

Also in the symmetrical system shown in Fig. 30,

$$H_R = -H_L = B\,S$$

If the constants and variables, such as messenger and trolley tensions, weights, and materials which determine the system shape in Fig. 29 are the same for Fig. 30, and if H_R (Fig. 30) is equal to H_R (Fig. 29) for the same value of x, then, if the two shapes are added

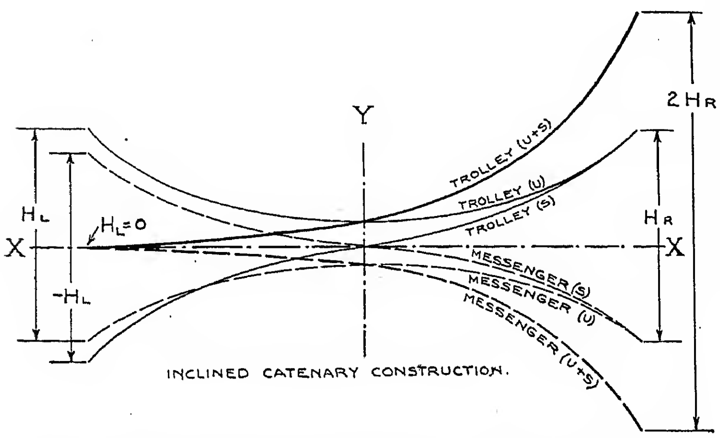

FIG. 32—THE COMBINED U AND S SHAPE, OR TRANSITION CURVE

together algebraically, a new shape similar to that shown in Fig. 32 is obtained, which is, as before, similar about the system axis, but which is no longer symmetrical about the H axis. The expression for this new shape is

$$H = A\,U + B\,S \tag{26}$$

It is clear that the shapes U and S may be combined with each other in any degree. If the factor B is zero, the shape S is not present; and the system has the shape shown in Fig. 29, which is for a symmetrical continuous curve. When A is zero, the shape U is not present,

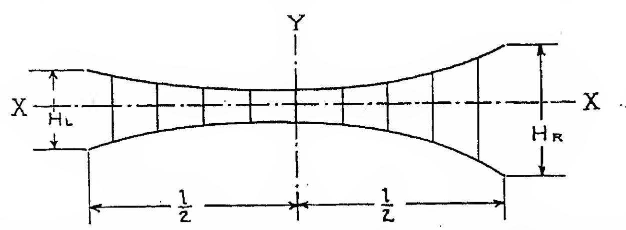

FIG. 33—INCLINED CATENARY WITH ASYMMETRICAL HORIZONTAL DISPLACEMENTS ABOUT LOW POINT

and the system has the symmetrical shape shown in Fig. 30, which is a reverse curve. When A and B are present to an equal degree, the system has the shape shown in Fig. 32, which is a transition curve of some kind.

Conversely, it is also clear that any continuous curve, as in Fig. 33, which is not symmetrical with respect to the H axis, that is, where the distance between the trolley and the messenger is not the same, for the same distance each side of the H axis ($H_R \gtrless H_L$) such a shape partakes of both shapes U and S.

The expression (**26**) may therefore be said to be the general expression for any combined horizontal system.

If U and S can be determined for a given system whose variables are known, the shape of any span on that system may be determined by the expression (**26**), by determining the values of their multipliers, A and B.

The Determination of the U Shape. Fig. 34 is that of a funicular polygon, whose shape is assumed to be symmetrical about its normal axis H. The forces P_0, P_1, P_{-1}, P_2, P_{-2}, P_3, P_{-3}, etc., are assumed to be acting on a system whose horizontal component of tension (parallel to the horizontal axis X) is T; and these forces are assumed to occur at equal intervals (s) along the X axis, and are all normal to that axis. $P_1 = P_{-1}$, $P_2 = P_{-2}$, $P_3 = P_{-3}$, etc., and P_0, P_1, P_2, P_3, etc., may be equal, or may progressively increase or decrease.

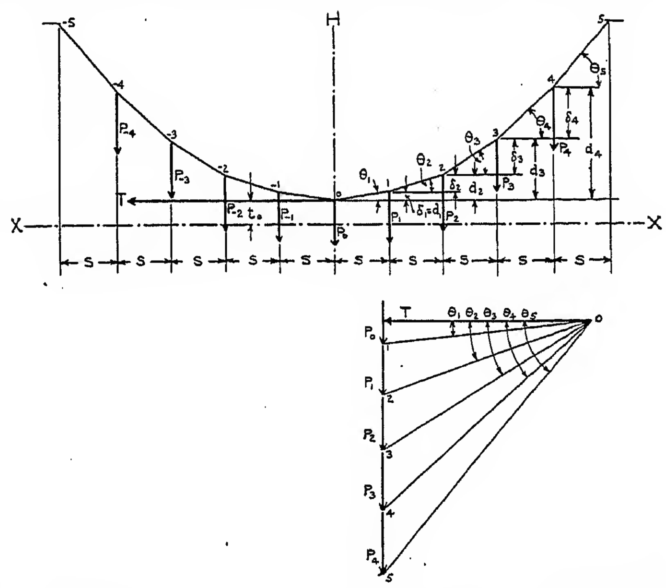

FIG. 34—THE FORCES AND DISPLACEMENTS IN A REGULAR SYMMETRICAL FUNICULAR POLYGON

The system will be deflected, due to these forces, at points 0, 1, 2, 3, 4, etc., and the angles made between the sides of the polygon, and parallels to the X axis, are θ_1, θ_2, θ_3, θ_4, and θ_5 respectively. For convenience, the stress diagram is shown below in the figure.

Let t_0 be the distance from the polygon to the X axis at its nearest point (0); let δ_1, δ_2, δ_3, δ_4, etc., be the departure measured normal to the X axis, due to θ_1, θ_2, θ_3, θ_4, etc.; and let d_1, d_2, d_3, d_4, etc., be the departures from a line drawn parallel to the X axis through the nearest point, 0.

Then

$$\tan\theta_1 = \frac{\delta_1}{s} = \frac{P_0}{2\,T} \text{ (in the stress diagram)}$$

and

$$\delta_1 = \frac{s}{T}\frac{P_0}{2}$$

Similarly,

$$\tan\theta_2 = \frac{\delta_2}{s} = \frac{\frac{P_0}{2} + P_1}{T}$$

and

$$\delta_2 = \frac{s}{T}\left(\frac{P_0}{2} + P_1\right),$$

and in like manner,

$$\delta_3 = \frac{s}{T}\left(\frac{P_0}{2} + P_1 + P_2\right)$$

and

$$\delta_n = \frac{s}{T}\left(\frac{P_0}{2} + P_1 + P_2 + P_3 + \ldots + P_{n-1}\right) \tag{27}$$

$$= \frac{s}{T}\,\Sigma\,P_n$$

where ΣP_n is the sum of all the forces, or pulls, acting on the system between the center and up to and including the point $n - 1$.

In like manner, for d

$$d_1 = \delta_1 \qquad = \frac{s}{T}\left(\frac{P_0}{2}\right)$$

$$d_2 = d_1 + \delta_2 = \delta_1 + \delta_2 \qquad = \frac{s}{T}\left(\frac{2\,P_0}{2} + P_1\right)$$

$$d_3 = d_2 + \delta_3 = \delta_1 + \delta_2 + \delta_3 \qquad = \frac{s}{T}\left(\frac{3\,P_0}{2} + 2\,P_1 + P_2\right)$$

$$d_4 = d_3 + \delta_4 = \delta_1 + \delta_2 + \delta_3 + \delta_4 \qquad = \frac{s}{T}\left(\frac{4\,P_0}{2} + 3\,P_1 + 2\,P_2 + P_3\right)$$

$$d_n = d_{n-1} + \delta_n = \delta_1 + \delta_2 + \delta_3 + \ldots + \delta_n \qquad = \frac{s}{T}\left(\frac{n\,P_0}{2} + (n-1)\,P_1 + (n-2)\,P_2 + \ldots + P_{n-1}\right)$$

$$= \frac{s}{T}\,Q_n \tag{28}$$

where Q_n is the expression in the parenthesis.

The distance, or ordinate, of any point on the polygon from the X axis is

$$t_n = d_n + t_0 \tag{29}$$

The forces and the figure just discussed must now be combined with the shape and the forces of the tangent catenary.

For calculation purposes, each hanger is reduced to the elementary form shown in Fig. 35.

In this figure,

v_n is the projection of any rod r_n on a vertical plane (calculated from expression (4)),

h_n is the projection of that rod on a horizontal plane,

P_n is the horizontal pull, or displacing force, acting on the lower end of the rod r_n,

W_n is the weight, or restoring force acting on the lower end of the rod,

t_n and m_n are the distances from the trolley and the messenger, respectively, to the system axis,

r_n is the theoretical length of the rod, and is the geometrical sum of v_n and h_n.

The inclination of the rod will be in the line of the resultant of P_n and W_n.

Then

$$P_n : h_n :: W_n : v_n$$

and

$$P_n = h_n \frac{W_n}{v_n} \tag{30}$$

Combining Figs. 34 and 35 gives Fig. 36, which is an isometric view of one-half of a symmetrical span of inclined catenary on a continuous curve.

The system axis divides the projection of each rod, h, into two parts, m and t, such that

$$\frac{t}{m} = \frac{M}{T}$$

The known constants of the catenary used for illustration are:

M = 3900 lb.
T = 3415 lb.
s = 10 ft.
W_0 = 13.36 lb.
v_0 = 0.448 ft.

t_0 is assumed to be unity.

The derived constants are

$$\frac{T}{M} = 0.876 \text{ and } \frac{s}{T} = 0.00293$$

also

$$h_0 = 1.876 \qquad \text{(from (22))}$$

$$\frac{W_0}{v_0} = 29.8 \text{ whence } P_0 = 55.9 \qquad \text{(from (30))}$$

$$\Sigma P_0 = \frac{P_0}{2} = 27.95 = Q_0 \text{ and } \frac{s}{T} Q_0 = 0.0819 = d_1$$

(from (**28**))

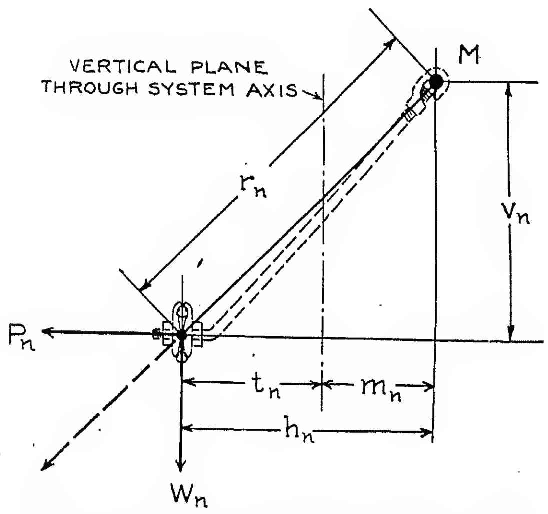

FIG. 35—INCLINED CATENARY CONSTRUCTION
Elements of hanger rods, contact, and messenger

Then, from (**29**), $t_1 = 1.0819$ which is the first point on the U curve. Continuing,

$$h_1 = 2.025 \qquad \text{(from (22))}$$
$$v_1 = 0.476 \qquad \text{(from (4))}$$
$$W_1 = 13.37$$

(Note: W will increase in accordance with a previous rough calculation of the weights of rods on an average curve (3 deg., using parabolic formula. The error made, leaving W constant, is very small.)

$$\frac{W_1}{v_1} = 28.1$$

$$P_1 = 56.9 \qquad \text{(from (30))}$$
$$\Sigma P_1 = 84.85 \qquad \text{(from (27))}$$
$$Q_1 = 112.8 \qquad \text{(from (28))}$$
$$d_2 = 0.331 \qquad \text{(from (28))}$$

and

$t_2 = 1.331$ from (**30**) which is the second point on the U curve.

In this manner, the calculations may be continued

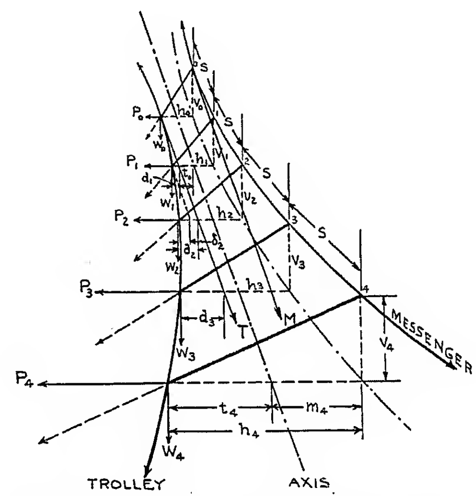

FIG. 36—INCLINED CATENARY CONSTRUCTION

The development of the U-shape for use on circular continuous curves. (See Table I)

until enough points are determined for the longest span to be used, 16 or 17 being ample for the maximum condition. A convenient form for setting up the calculations is shown in Table I.

The points may then be plotted, with reference to an

X and a U axis. It will be symmetrical about the U axis, and will always be positive, for any value, positive or negative, of x.

The Determination of the S Shape. The method used for determining the S shape is practically identical with that used for determining the U shape, as outlined above, with one or two exceptions. Fig. 37 shows an isometric diagram of half of a symmetrical span of inclined catenary on a reverse curve. It will be seen that the shortest rod in this diagram is not inclined; therefore $h_0 = t_0 + m_0 = 0$, and no assumptions can be made as to their value, to start the calculations, as in the case of the U curve.

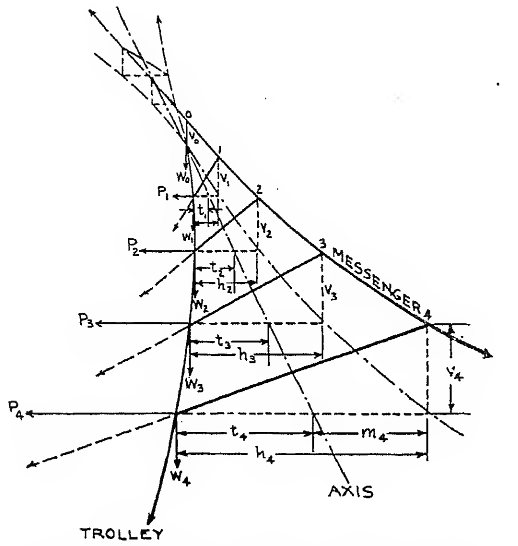

Fig. 37—Inclined Catenary Construction

The development of the S-shape for use on reverse curves and transitions. (See Table II)

A convenient value can, however, be assigned to the deflection at the next adjacent rod, with which assumption, and the same constants used in the calculations for the U curve, the calculations may be made, point by point, until the same number has been determined as for the U curve. These are shown tabulated in Table II.

Notes: (a) Assumed, to start calculations.
(b) Calculating backwards from starting assumption.
(c) Due to component of pull of other half of span.

On this curve, $t_n = d_n$ and when calculated from the assumed value of d_1 their values may not be anything like the values of t in the U curve. When they are all determined, however, the value of d at any point (for example, at point $x = 100$) may be multiplied by a factor which will make it the same as the value of U for that point. Then if all the other values of d are multiplied by the same factor, the new curve will still have the S shape, but will be of a magnitude which can be conveniently compared with the U curve.

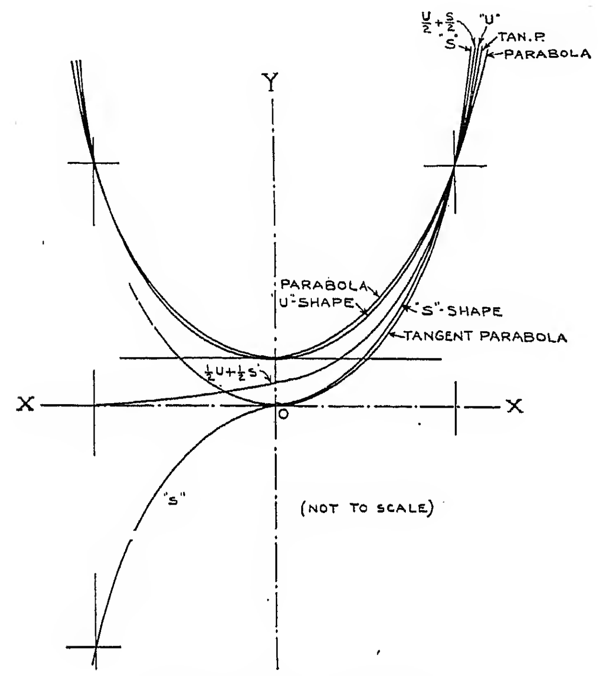

FIG. 39—INCLINED CATENARY

Comparison of U and S shapes with parabola. (See Table III)

The values of S are negative for negative values of x. Both curves are shown, plotted to scale for the determination of intermediate values, in Fig. 38.

COMPARISON OF THE U SHAPE AND THE S SHAPE WITH THE PARABOLA

Having determined the ordinates of the shapes U and S, they may now be compared with each other and with the parabola, which is the assumed shape of the track curve on ordinary curves and span lengths. If, by a proper choice of multipliers, these three curves are plotted for a given span, so that the U curve and the parabola are tangent to each other at the $f(x)$ or Y axis and all three curves have the same ordinate for $x = l/2$, it will be seen that the U curve lies outside the parabola from the point of tangency at the center until it crosses the parabola at the end of the span ($x = l/2$), and is inside thereafter.

The S curve passes through the origin, and, for positive values, lies closely outside of the U curve, crossing it and the parabola at the end of the span, and remaining inside of both curves thereafter; see Fig. 39. The amount of departure from the parabolic shape may best be seen from the tabulated values of the ordinates of the three curves, shown in Table III, calculated for equal values of all three curves for $x = 100$.

The U Shape and the Parabola. It will be noted that the maximum difference between the U shape and the parabola occurs at about $x = 60$ and that this difference is 0.23 units. If the value of the ordinate at $x = 100$ represents feet, then the maximum departure from the track shape is 0.23 ft., or less than three in. The curve having a middle ordinate of 10.46 ft. for a 200-ft. span is approximately 12 deg., which is a very extreme curve for this span. A four-deg. curve having one-third this ordinate for the same span would therefore have a maximum variation of not more than one inch between the shape of the track and the U shape for any point between the center of the span and the support.

For points outside the span ($x > l/2$) this difference increases very rapidly; so that for this reason, if for no other, the ordinates calculated for a short span should not be extrapolated and used on a longer span without careful investigation of the departure from the track curve.

It is clear, therefore, that the U curve (at least for the particular constants used for illustration) very closely approximates the assumed shape of the track curve, and presents no serious limitations on account of such departures as exist, at least for points within the span used for calculations.

The S Shape and the Parabola. It is obvious that the S shape is only used alone on reverse curves. These are rarely circular, but spiral, so that no accurate comparisons can be made. In general, however, it may be seen from the tabulated values in Table III, that for points near the end of the

TABLE III

span, where the track begins to approach the parabolic or circular shape, the values are very nearly the same as for the U-shape. For comparison at the point of reverse curvature (the origin), it is necessary to shift the parabola tangent to the X axis. The values of the

ordinates to the tangent parabola are also given in Table III, and from them it is seen that the maximum departure is for approximately $x = 30$. On a four-deg. curve, the indicated difference would be less than two inches.

If both shapes are present in equal amount, making the transition shape referred to in Fig. 32, it will be seen in like manner from the tabulated values of the ordinates of $U/2 + S/2$, also shown in Table III, that for the half of the span which lies on the curve, the variation from the tangent parabola is not more than

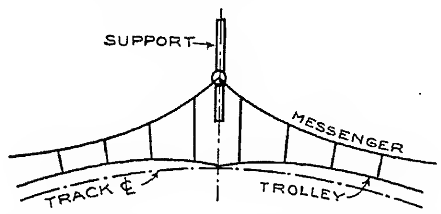

Fig. 40—Illustrating the Cusp at the Support when Contact Wire has Same Middle Ordinate as Track Curve, Inclined Catenary

0.65, at approximately $x = 20$. Reduced to a four-deg. curve, this would not exceed three inches.

This combination is where the greatest departure from the assumed track shape exists, and also the place where the greatest variation in track alinement may be expected, since most railroad curves are spiralled at the points of tangency and points of curvature. For these reasons it is sometimes well to make a set of field measurements of actual track departures from the tangent, on such spans, for comparison with the trolley curve shape, when designed.

The above differential values are, of course, true only for the catenary design used for illustration, but they may be taken as being representative; and in general, within the limits of reasonable application, these shapes do not, *within the span*, present serious limitations either used alone or in combination.

The most important limitation due to the shape of both the U curve and the S curve, occurs at the point of support or end of the span, where on account of the progressive increase in the curve pull with the span length, all the curves are sharper than the track curve, and cross it at this point, as indicated in Fig. 39. On long spans and short radius curves this will produce an irregularity, or cusp, between spans, as shown in an exaggerated manner in Fig. 40, which may spoil the appearance. Since this is due to the increase in curve pull, it is a function of the span length, and may be obviated by making the radius of the trolley curve at the point of support (or at the last hanger) equal to the radius of the track curve which is being fitted, instead of having the trolley curve tangent to and equal to the track curve at the center of the span.

The radius of the trolley curve (R_n) at the support may be determined by using the unit curve-pull, p_n, which is the value of P for any value of x in Table I or II, divided by the hanger spacing s, and substituting in the expression, derived from (**16**),

$$R_n = \frac{T}{p_n} \qquad (31)$$

The radius of the track curve (R_T) may be known, or may be found by substituting known values in the parabolic expression (**11**) for the middle ordinate

$$R_T = \frac{l^2}{8\,\overline{MO}} = \frac{l^2}{8\,d} \qquad (32)$$

where d is that of the U shape, taken from Table I.

The ratio

$$K = \frac{R_n}{R_T} \qquad (33)$$

will be constant for a given span length, and must enter into the calculation of the "multiplier" A in order to avoid the irregularity at the point of support. It represents the proportion of the track middle ordinate which must be taken to make the U shape have the same radius as the track, at the end of the span. This constant changes with the span length, and may be calculated from the U shape curve-pulls, and plotted for convenience, as shown in Fig. 41.

In a similar manner, it may be shown by a compari-

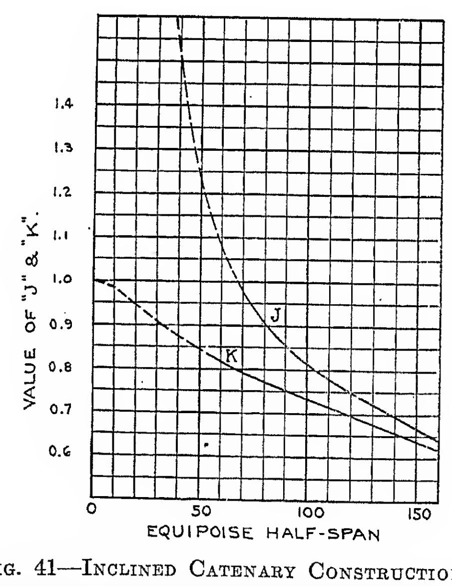

Fig. 41—Inclined Catenary Construction

Correction factors to be used with multipliers A and B of the shape factors U and S. They are the ratio $R\,n/R_T$

son of the S shape with the "tangent parabola," that these curves may be made parallel or tangent, of equal radius, at the point of support by using a similar constant J for a given span length, which is determined in a like manner from the curve-pulls calculated from Table II.

This constant

$$J = \frac{R_n}{R_T} \qquad (34)$$

is quite different from K because the rate of change of the curve-pull is different for the two shapes U and S. It changes as the span, and may be plotted with the corresponding values of K as shown in Fig. 41.

The necessity for using these constants to improve the shape at the point of support in reality limits the length of span on a given curve, since it is apparent that the middle ordinate (d_T) of the trolley curve should not be less than the track $\overline{MO}$ by an amount greater than the maximum allowable departure from the center-line of the pantograph. Allowing three in. either side for all other possible variations, the allowable departure due to this factor should not be greater than 12 in. total, or 6 in. either side of the pantograph centerline.

Then

$$\overline{MO} - d_T = 2\,q \tag{35}$$

The trolley curve will lie across the curve of the pantograph centerline as shown in Fig. 42.

The Determination of the Multiplier A for the U shape. Assume the symmetrical construction shown in Fig. 29 on a railroad curve of radius R, with a span length l having the low point in the center of the span. H is

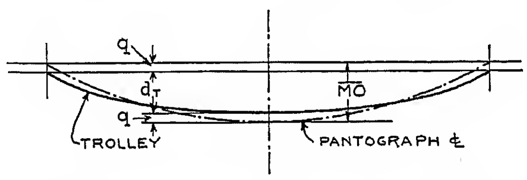

FIG. 42—INCLINED CATENARY CONSTRUCTION

Relative position of trolley curve and pantograph center-line when cusp at support is eliminated

the horizontal distance between the trolley and the messenger at the point of support. By construction, the S shape is not involved,

whence,

$$H = A\,U$$

but

$$H = d_T + d_M + h_0 = d_T\left(1 + \frac{T}{M}\right) + h_0 \text{ from } \mathbf{(19)}$$

Then

$$A\,U = d_T\left(1 + \frac{T}{M}\right) + h_0 \tag{36}$$

On the U curve, the ratio of any ordinate h_n to the shortest ordinate h_0 is

$$\frac{h_n}{h_0} = U \tag{37}$$

or

$$h_n = h_0\,U$$

If

$$h_n = H$$

then

$$H = h_0\,U$$

and

$$h_0 = A \tag{38}$$

In other words, on symmetrical curves involving the U shape only, the multiplier A is in reality the horizontal length of the shortest hanger at the center of the span.

Substituting **(38)** in **(36)**,

$$h_0\,U = d_T\left(1 + \frac{T}{M}\right) + h_0$$

or

$$h_0\,(U - 1) = d_T\left(1 + \frac{T}{M}\right)$$

and

$$h_0 = \frac{d_T\left(1 + \frac{T}{M}\right)}{U - 1} = A \tag{39}$$

If d_T, the middle ordinate of the trolley curve *is the same value* as $\overline{MO}$, the middle ordinate of the track, then, using expression **(11)** for the $\overline{MO}$,

$$h_0 = \frac{\frac{l^2}{8\,R}\left(1 + \frac{T}{M}\right)}{U - 1} = A \tag{40}$$

But it has previously been shown that a proportion $\frac{R_n}{R_T}$ of $\overline{MO}$ (equal to $K\,\overline{MO}$) must be used, instead, to prevent a cusp at the support.

Then

$$h_0 = \frac{\frac{K\;l^2}{8\,R}\left(1 + \frac{T}{M}\right)}{U - l} = A \tag{41}$$

The Determination of the Multiplier B for the S Shape. Assume the symmetrical construction shown in Fig. 30 on a reverse track curve of radius R with a span length l, having the low point over the point of reverse curvature. H is the horizontal distance between the trolley and the messenger at the point of support. By construction, the U shape is not involved.

Therefore

$$H = B\,S$$

but

$$H = d_T + d_M = d_T\left(1 + \frac{T}{M}\right)$$

and

$$B = \frac{d_T\left(1 + \frac{T}{M}\right)}{S}$$

If d_T, the middle ordinate of the trolley curve, is regarded as part of a continuous curve having the same middle ordinate as the track curve, also regarded as continuous,

then

$$B = \frac{\frac{l^2}{8\,R}\left(1 + \frac{T}{M}\right)}{S}$$

But it has previously been shown that to avoid the cusp at the support, a certain proportion J must be used instead,

whence

$$B = \frac{\frac{J\,l^2}{8\,R}\left(1 + \frac{T}{M}\right)}{S} \tag{42}$$

The Application of the U Shape to Standard Hangers. Having determined the shape U and the value of the multiplier A in terms of a given span and curve, the horizontal lengths of all the rods may now be calculated.

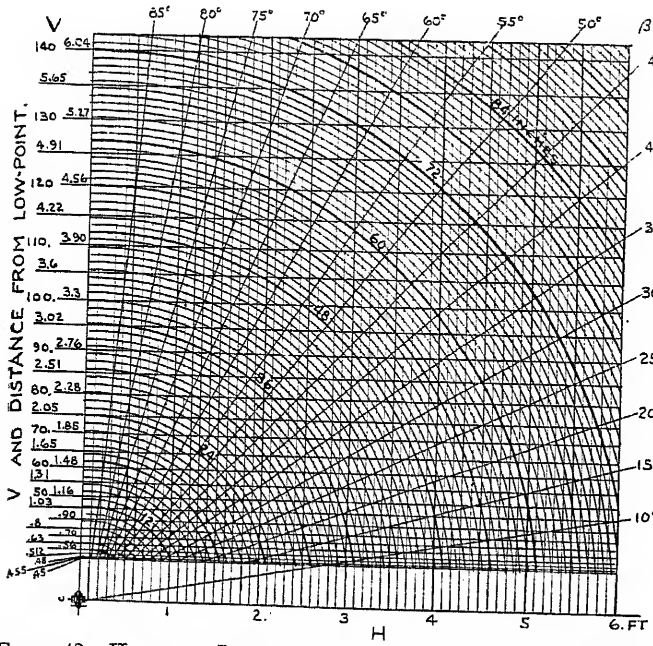

Fig. 43—Hanger Length Chart. Inclined Catenary Construction

For example, to calculate standard hangers for a 250-ft. span on a 2-deg. curve:

K = 0.685, from Fig. 41,
l = 250,
R = 2865, T = 3415, M = 3900,
$U - 1$ (for $x = 125$) = 15.5, from Fig. 38 or Table I,
$\overline{M\,O}$ = 2.73, $K\,\overline{M\,O} = 1.87 = d_T$,

$\overline{M\,O} - d_T = 0.86$, which is within the allowable variation, 1 ft.

Substituting the above values in (**41**),

$$A = 0.236$$

Multiplying each value of U in Table I by this value of A will give the horizontal length of the rods at the corresponding distance x from the low-point. The value of $A\,U$ for $x = 125$ gives the horizontal separation between trolley and messenger at the support. In this case,

$$H = 16.50 \times 0.236 = 3.9 \text{ ft.}$$

The horizontal values of each rod thus determined may now be combined with their vertical projection, which is assumed to be the same as standard tangent rods. A chart similar to Fig. 43 saves a great deal of calculation, and gives at once the true length of the rod and its angle of inclination β to the horizontal.

If care has been taken in locating the supports so as to maintain "standard hangers" as outlined in Part I, at the same time maintaining as far as possible a fair degree of uniformity in the span lengths on curves of approximately the same radius, inclined hangers may be designed as outlined above for several different average degrees of curvature, using the maximum span for a given curve in each case.

On the Danbury Branch, hangers were designed in this manner for 1-deg., 2-deg., 3-deg., and 4-deg. curves having spans of 250 ft., 200 ft., 180 ft., and 190 ft., respectively. These were approximations when applied to shorter spans, or to intermediate curves, but care was taken that allowable limits were not exceeded. A further approximation was made in the design of these hangers in that after calculating the various values of h_0 for the shortest rods at the centers of the spans on the various curves, an adjustment was made in these values such that all the shortest rods had the same average length and the same average inclination.

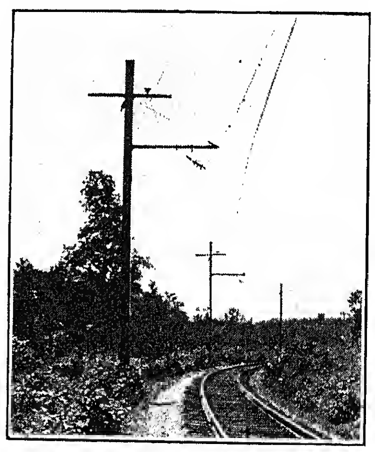

Fig. 44—Inclined Catenary on Four-Deg. Curve, Danbury Branch, 1925

The design of a transition span was also included in this approximation, so that the resulting standard hangers could be used, within limits, for construction over most of the curves as well as the transitions. This did not make perfectly level wire, but the variations were less than the allowed variation due to temperature changes, and by this method a large amount of calculation was done away with. On curves above four deg. up to six deg., four-deg. rods were used, and the trolley was deflected at the supports by pull-offs, somewhat as on tangent-chord construction. Fig. 44 shows the appearance of the completed con-

struction on curves where the rods fitted the track curve, and Fig. 45 illustrates the pulled-off construction on sharper curves. On one or two curves which were sharper than four deg., the rods were calculated to individually fit the track curve.

Computation of Special Spans, Involving both Shape Factors. On transition curves, reverse curves, or where there is a large difference between the horizontal separations of messenger and trolley at each end of the span, the values of these offsets H_R and H_L are usually known. These values may be substituted in the general expressions

$$H_R = A\,U + B\,S \qquad \text{at } x = n_1$$
$$H_L = A\,U + B\,S \qquad \text{at } x = -\,n_2$$

using the values of U and S given for $x = n_1$ in the case of H_R and those given for $x = -\,n_2$ in the case of H_L, and having proper regard for the signs of U and S. U is always positive for values of x either side of the low-point and S is positive for values of x to the right of the low-point, and negative for values of x to the left of the low-point.

The above equations may be solved simultaneously for A and B, and these, when determined with proper regard for the factors K and J and used with their respective shape factors, will give the horizontal length h_n of any rod, which may be combined with v by use of chart shown in Fig. 43, or otherwise.

All the above calculations are based on combining the horizontal lengths of the rods with "standard" tangent hanger values of v. If vertical lengths other than "standard" are used, the shape factors U and S calculated for standard hangers will not apply, but new values of the U shape and the S shape, based on the shortest "special" rod, must be calculated. This greatly increases the amount of calculation work, and for this reason, "special" hangers should be avoided on curve construction where possible.

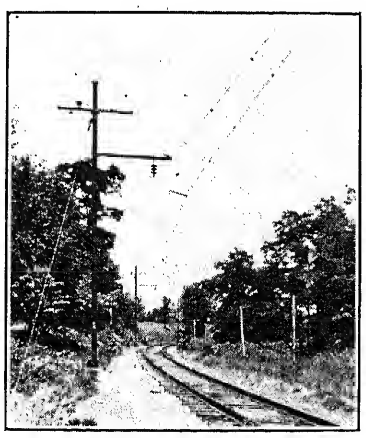

FIG. 45—INCLINED CATENARY ON FIVE-DEG. CURVE, DANBURY BRANCH, 1925

Showing four-deg. catenary pulled off at supports

The above methods and calculations as set forth are somewhat complex, but once developed for a given design, they may be easily applied to the solution of any standard span.

The Limitation of Inclined Construction. Some of the limitations of the inclined construction have already been touched upon, the most important being the necessity of using a factor in the calculation of the "multipliers" to avoid the cusp in the shape of the trolley wire at the point of support. The span limit is reached for a given curve, when the difference between the track middle ordinate and the trolley middle ordinate is greater than 1.0 ft.

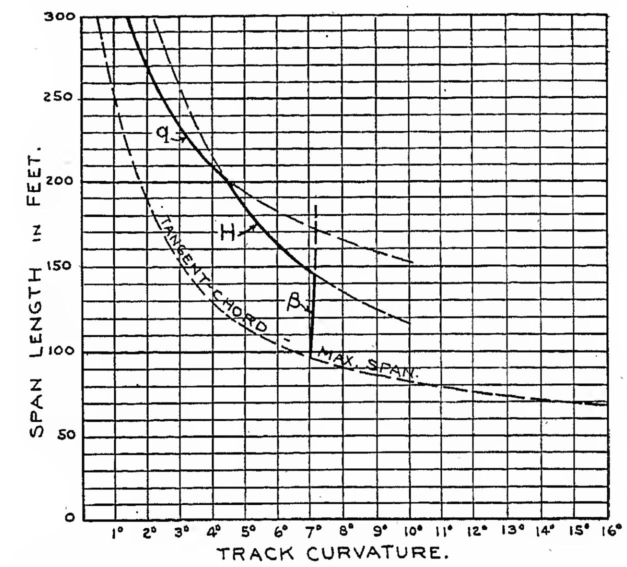

FIG. 46—MAXIMUM SPAN-LIMITS FOR 9/16-IN. INCLINED CATENARY FOR VARIOUS CURVES

Another important limitation is the maximum permissible horizontal length of longest rod, or the offset at the support. Good practise indicates a limit for this of about six ft., except in special cases which cannot otherwise be avoided, to avoid construction which would extend over the adjacent parallel track which is usually a different electrical section.

A third important limitation is that due to the inclination of rods. When the angle of inclination to the horizontal is too small, the plane of the hanger rods approaches that of the pantograph, already inclined on curves on account of super-elevation of outer rail. Good practise indicates a limit to this inclination of approximately a horizontal value of three to a vertical value of one, except in special cases.

These limitations may be shown graphically for comparison with the limitations of tangent-chord construction, as shown in Fig. 46, where q is the span limitation due to the difference between track and trolley middle ordinates, H is the span limitation due to maximum allowable offset between trolley and messenger at the support, and β the span limitation due to hanger rod inclination. From this diagram it is seen that the practical application of the inclined catenary con-

struction is limited to curves up to about seven deg. Above this point, tangent-chord construction is preferable.

Determination of Structure Heights. As in the case

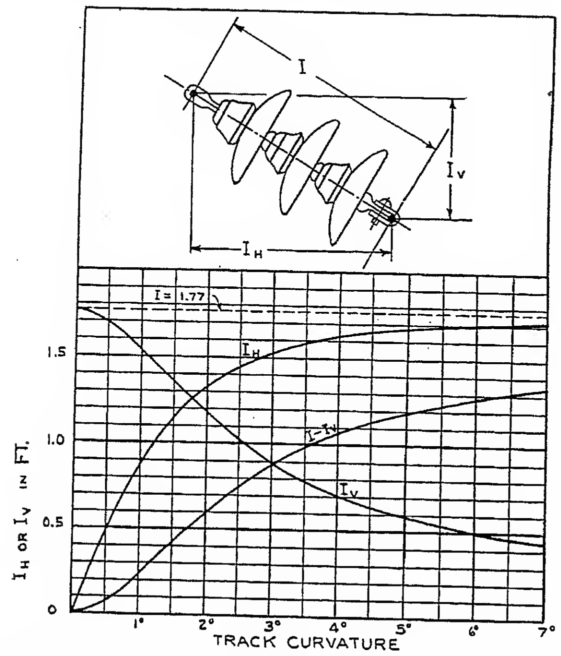

FIG. 47—INSULATOR INCLINATION—INCLINED CATENARY FOR VARIOUS CURVES

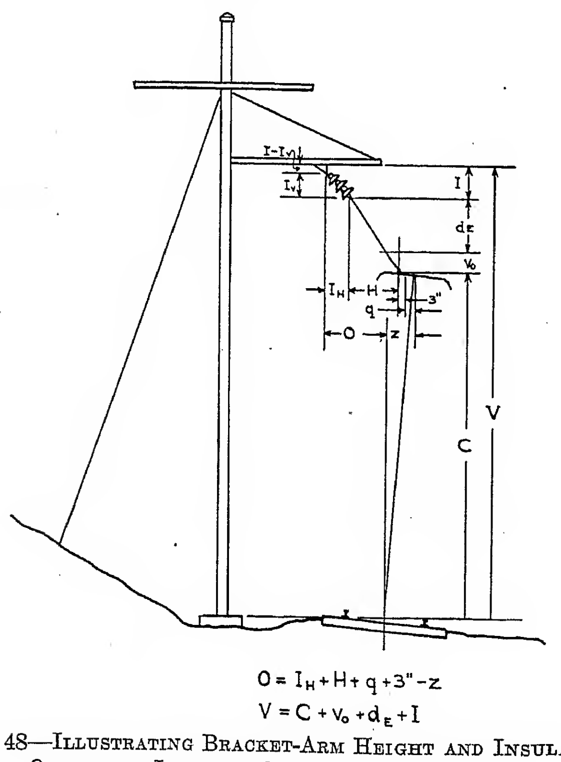

O = I_H + H + q + 3" − z

V = C + V_0 + d_E + I

FIG. 48—ILLUSTRATING BRACKET-ARM HEIGHT AND INSULATOR OFFSET ON INCLINED CATENARY CONSTRUCTION

of tangent-chord construction, the structure height is given by formula (6)

$$V = C + v_0 + d_E \pm I$$

If suspension insulators are used, and this type is preferable on account of the horizontal stresses, they may assume an inclination which is the resultant of the weight supported and the curve-pull, W and P, respectively. If I_V and I_H are the vertical and horizontal projections of the inclined insulator assembly, then

$$\frac{I_V}{I_H} = \frac{W}{P} = \frac{\gamma\, l}{l\left(\dfrac{T + M}{R}\right)} = \frac{\gamma\, R}{T + M} = \frac{\gamma}{p} \qquad (43)$$

In other words, the inclination is independent of the

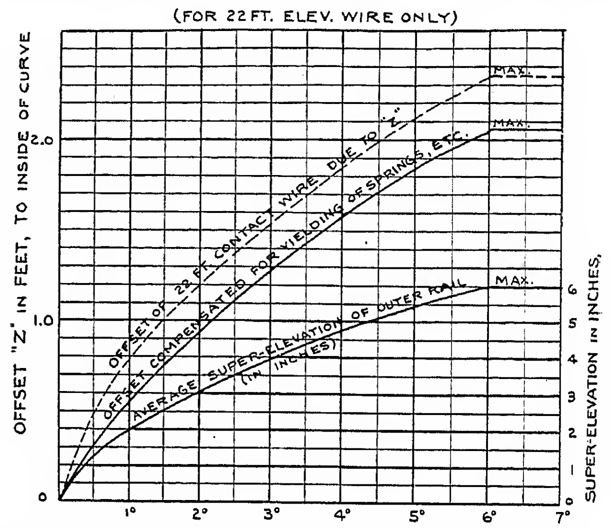

FIG. 49—AVERAGE SUPER-ELEVATION OF OUTER RAIL ON VARIOUS CURVES, WITH CORRESPONDING OFFSET z OF 22-FT CONTACT WIRE

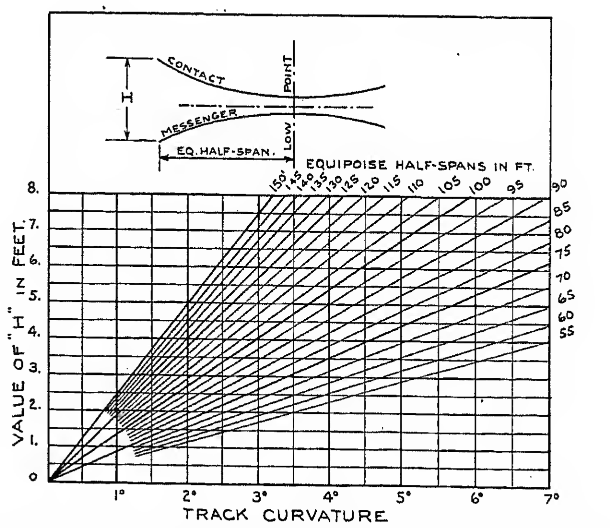

FIG. 50—HORIZONTAL DISPLACEMENT OF MESSENGER FROM CONTACT FOR INCLINED CATENARY AT SUPPORT, FOR VARIOUS SPANS AND CURVES

span length, and is the ratio of the unit weight of the catenary to the unit curve-pull; and since γ, T, and M are constant, is directly proportional to the curvature. A set of curves giving the values of I_V, I_H, and $(I - I_V)$ is very useful in determining structure heights and insulator offsets. $I - I_V$ is useful to determine the

spacer length between the supporting structure and the top of the insulator when the same height structure is maintained with inclined construction as on tangent construction. Fig. 47 shows such curves.

Determination of Insulator Attachment Offsets form Track Centerline. The super-elevation of the outer rail will cause an offset z of the pantograph centerline

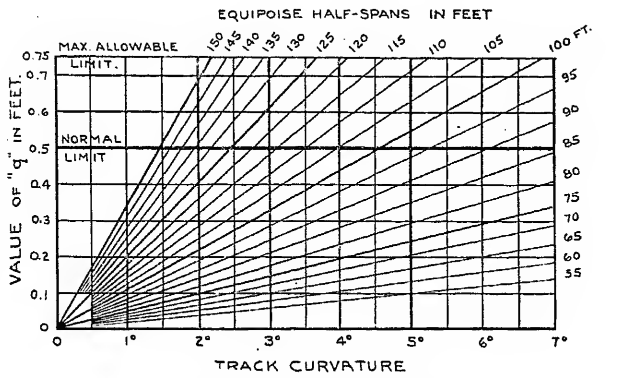

Fig. 51—Inclined Catenary

Maximum departure of U-shape of contact wire from shape of track at center of span on circular curves for radius of contact wire equal to radius of track curve under support; for various spans and curves

from the track centerline, as in tangent-chord construction, towards the inside of the curve. A small amount, generally about three in., is also allowed for the yielding toward the outside of the curve of pantograph and locomotive springs, due to centrifugal action at running speeds.

The messenger has a horizontal separation H from the trolley wire, toward the outside of the curve.

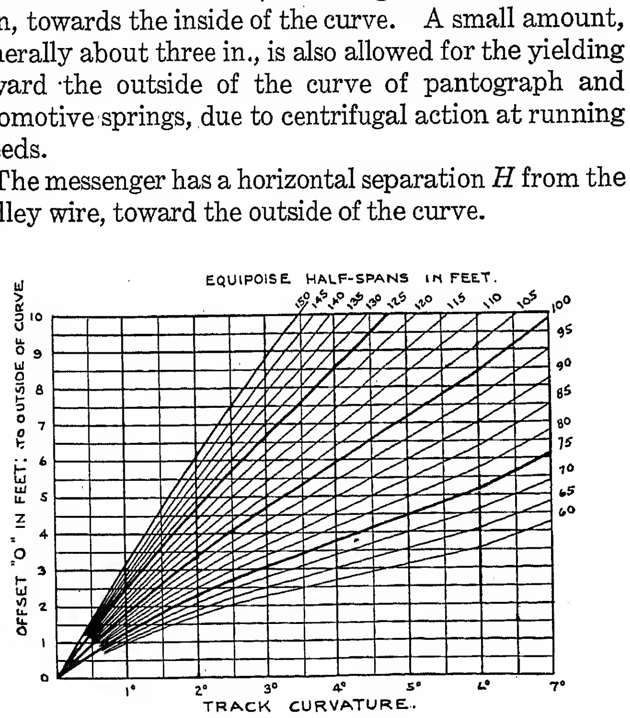

Fig. 52—Total Offset of Insulator Attachment for Inclined Catenary Construction, for Various Spans and Curves Under Normal Conditions

The insulator, if inclined, will increase the offset to the outside of the curve by the value of I_H.

If the curve of the wire is desired to follow the pantograph centerline curve as shown in Fig. 42, an additional offset to the outside of the curve of the value of q must be made.

Adding all these elements, the total offset from the track centerline is

$$O = I_H + H + q + 3'' - z \qquad (44)$$

diagrammatically shown in Fig. 48, which is typical of inclined catenary pole and bracket construction on curves.

It is very useful to have these various elements plotted for standard conditions on various curves. Fig. 49 shows values of z plotted for wire 22 ft. above rail, from known super-elevations for different degrees of curvature, and compensated for the allowance assumed for pantograph and spring yielding.

Values of H for standard spans for various curves are

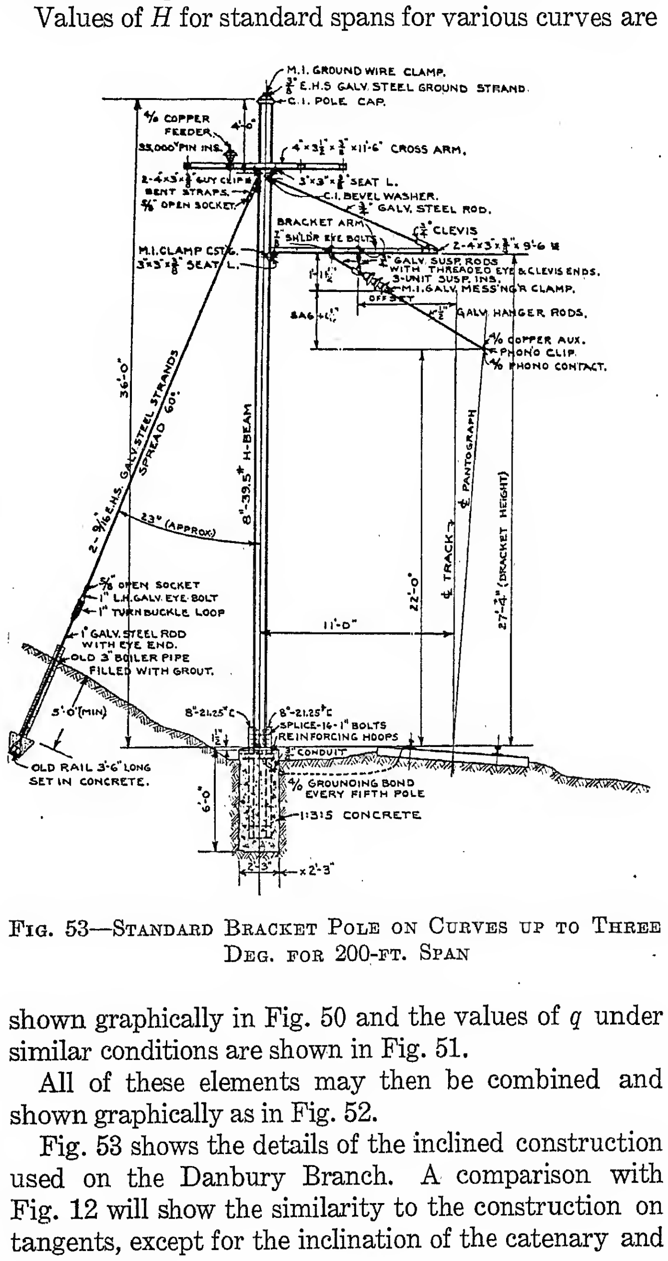

Fig. 53—Standard Bracket Pole on Curves up to Three Deg. for 200-ft. Span

shown graphically in Fig. 50 and the values of q under similar conditions are shown in Fig. 51.

All of these elements may then be combined and shown graphically as in Fig. 52.

Fig. 53 shows the details of the inclined construction used on the Danbury Branch. A comparison with Fig. 12 will show the similarity to the construction on tangents, except for the inclination of the catenary and the insulator.

Advantages of Inclined Catenary Construction. It is readily seen from Fig. 46 that longer spans are permissible on all curves with inclined construction than with tangent-chord construction. This decreases the cost of supporting structures.

The necessity for pull-offs is largely eliminated, none generally being required for curves up to four deg. This means fewer insulators, an important point where high voltage is used on the contact system.

Sharp deflections in the contact wire, which tend to cause sparking and ultimate wear and injury to the wire, are avoided.

The contact system has greater flexibility than with tangent-chord construction, and hard spots are practically eliminated.

The variation in tension in the trolley wires due to temperature changes will, in general, be less than on tangent-chord construction, since there are no fixed points and the wire can move in and out on the curve as the tensions tend to vary, by swinging about the insulator support. This is a possible disadvantage, as will be mentioned below.

A closer approximation to the track centerline may be made with this type of construction, decreasing the chances of the pantograph leaving the wire under abnormal conditions.

The appearance of this type of construction is very pleasing to the eye and harmonizes very well in perspective with the track curve. This is not of especial value, but is in keeping with the desire, especially in highly improved suburban residential territory, to have the railroad property present an appearance in keeping with its surroundings.

Disadvantages of Inclined Catenary Construction. One of the greatest disadvantages of the inclined construction is its tendency for the contact wire to move about the attachment to supporting structures due to changes of tensions with temperatures. At low temperatures, this causes the wire to rise and to move in towards the center of the curve. For this reason, the insulators should be attached to a fixed point and not to a member which through its own motion, may augment this tendency. If pull-offs are used, as on sharper curves, it is better to apply them so that they fix the lower end of the catenary suspension insulator as well as hold the contact wire in position.

On the short, sharp curves generally found in terminals, yards and sidings, and cross-overs, the inclined catenary is difficult to design, install, and maintain on account of the deflector and sectionalizing details, and should not be applied to such track.

The complexity of design is possibly another disadvantage, but this is largely academic. The fact remains, however, that this type of construction does require more time for study of conditions and for the proper design than does tangent-chord construction.

The cost of installation is possibly higher than the cost of tangent-chord construction, but this is usually compensated for by a saving in the cost of supporting structures.

Although on heavy curves, longer spans may be used than with tangent-chord construction, the extreme flatness of the inclined construction in such cases is generally a greater disadvantage from construction, operation, and maintenance points of view than the additional pull-offs required with tangent-chord construction. As an illustration, the offsets under such conditions may be so great that on multiple track construction, to replace a faulty insulator on one track, it might be necessary to de-energize an adjacent track before the work could be done with safety.

Although it is very desirable to have a flexible contact system, when the construction is flat, as on heavy curves, there is very little reaction against the pantograph pressure, and if there are several pantographs acting in unison, as on multiple-unit trains, the contact wire may rise and still further reduce the clearance between the hangers and the pantographs.

Installation Methods. The same methods of installation may be used as for tangent-chord construction, although it is obvious that until loaded, the messenger will present greater problems of unbalanced stresses between tangents and curves with the inclined construction. For this reason, the writer prefers the method of installation which allows the tensioning of the messenger with the trolley wires approximately in position and in tension, held to the messenger by a few temporary ties per span. This saves further lengthy calculations for unloaded messenger sags under no-load stress conditions which will vary considerably on various curves from the stress on tangent.

In this analysis certain assumptions may have been made which may not be strictly true; as, for instance, the rods are in reality radial to the curve, instead of being parallel to each other. The errors due to such assumptions are, for the most part, very slight; or if important, the limits beyond which the assumptions do not hold are clearly established. There are possible short cuts to some of the formulas set forth which could be made by the use of exponential functions and the calculus, but it has been the intention to keep the mathematics as simple as possible.

Different design details may require different graphical exposition. The curves shown are merely to illustrate methods which the writer has found to be of great value in the design of various types of catenary construction for overhead contact systems.

Acknowledgment

The writer is greatly indebted to Mr. R. P. Winton, now Catenary Engineer of the Norfolk and Western Ry., for many valuable ideas during the past few years, which have been used and incorporated in the development of the theory and methods used in this discussion of the inclined catenary; and to Mr. Sidney Withington for many helpful suggestions in the preparation and arrangement of this paper.

Symbols Used

a area cross-section, wire or strand,

d deflection or sag of wire or strand,

f function f of x,
h horizontal projection of hanger rod length,
l distance between supports; span length,
l_E equipoise span,
$\frac{l_E}{2}$ equipoise half-span,
m horizontal distance from messenger to axis,
p unit curve pull,
q allowable departure from pantograph centerline,
s hanger spacing,
t distance (horizontal) from trolley to axis; temperature in deg. fahr.,
v vertical projection of hanger rod length,
x distance along system axis from low point of span,
z offset of trolley from track centerline due to super-elevation of outer rail,
A the "multiplier" of the shape factor U,
B the "multiplier" of the shape factor S,
C height of contact wire above top of rail,
D degree of curvature,
E Young's modulus of elasticity,
F function F of x,
H horizontal distance between messenger and trolley at support,
I length of insulator assembly,
I_V projection on vertical plane of inclined insulator assembly.
I_H projection on horizontal plane of inclined insulator assembly,
J the value of the ratio R_n/R_T of the S curve,
K the value of the ratio R_n/R_T of the U curve,
L length of messenger for span length l,
M horizontal component of messenger tension,
$\overline{MO}$ middle ordinate of a circular curve for a given span,
O offset of insulator attachment from track centerline at support,
P curve pull; horizontal force,
Q the sum of a series,
R the radius of a curve,
S the function $F'(x)$; the shape of the reverse or S curve,
T the horizontal component of trolley tension,
U the function $F(x)$; the shape of the continuous or U curve,
V height of supporting structure,
W vertical force due to weight,
X the system axis,
Y the axis of $F(x)$, perpendicular to the system axis through the low-point,
α coefficient of linear expansion,
β angular inclination of hanger rods from the horizontal,
γ unit weight (per unit length),
δ linear displacement,
Δ a change in value; increment or decrement,
θ angular displacement.

Catenary Construction for Chicago Terminal
Electrification of Illinois Central Railroad

BY J. S. THORP[1]

Non-Member

Synopsis.—The object of this paper is to give briefly the procedure followed by the Illinois Central engineers in the layout, design, and erection of the catenary system. Brief reference also is made to the principal items of material entering into the construction and to methods of maintenance.

* * * * *

THE Illinois Central decided upon the 1500-volt d-c. system of electrification with catenary construction for pantograph operation.

The electrified suburban trackage includes about:

4 route mi. of single main line track,
20 route mi. of double main line track,
1½ route mi. of 3 main line tracks,
8 route mi. of 4 main line tracks,
5 route mi. of 6 main line tracks, and about
20 track mi. of yards and sidings.

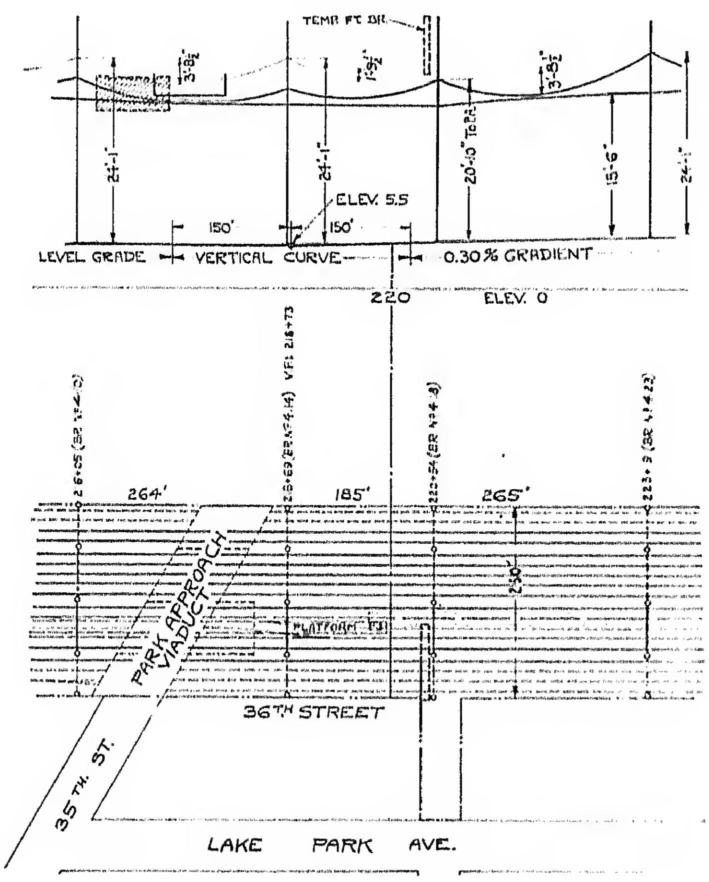

Fig. 1—Typical Track Plan

Plans

Track plans were prepared showing the existing tracks and the proposed track arrangement to ultimately develop the right-of-way. Fig. 1 shows a typical section of the track plan in the vicinity of 36th Street.

The catenary structures were located tentatively on the track plans, adhering to the normal tangent spacing of 300 ft. as far as possible and reducing the spacing according to Fig. 2, where the span is wholly or partly on

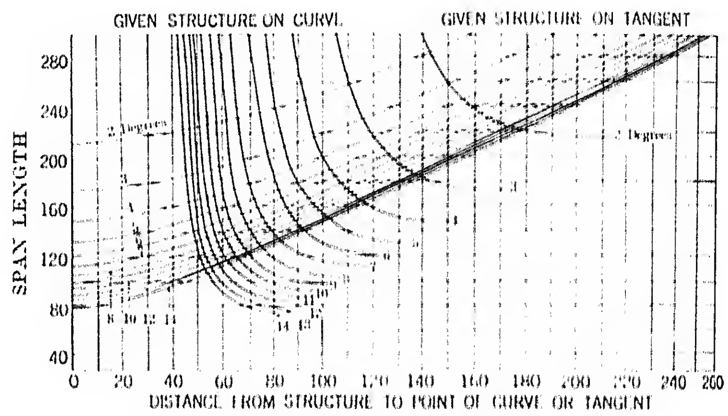

Fig. 2—Spacing Chart for Structures on Curves

a curve, or the normal spacing maintained and pull-off-poles interposed as found desirable. These locations were given to the field engineer who first made a check to see if any shifting would be necessary due to physical obstructions not shown on the plans, and then when the structures were definitely located, made cross-

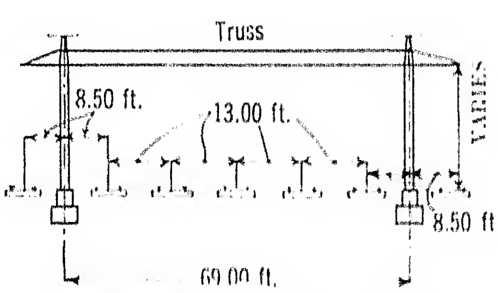

Fig. 3—Typical Erection Diagram

sections of the entire right-of-way at each location. From the track plans and cross-sections, erection diagrams as shown in Fig. 3 were prepared and the catenary structures designed. The height of the structure is determined by the catenary profile which is drawn on the track plans.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

Catenary Structure Foundations

The foundations of all permanent structures were concrete. Where the space between the ties was less than the across-track dimension of the foundation, "side-bearing" footings were used. These "side-bearing" footings were designed in accordance with the chart shown in Fig. 4.

Gravity type footings were installed where track shoreing was not necessary, and this type was designed

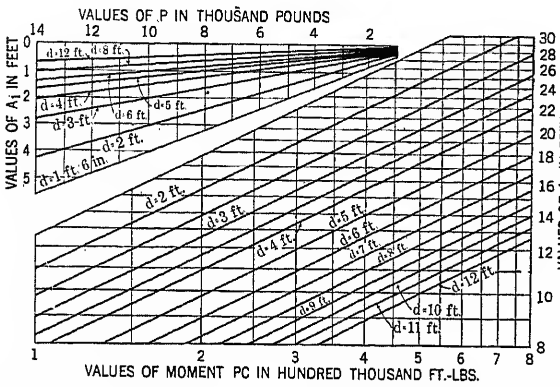

Fig. 4—Chart Used in the Design of Side-Bearing Foundations

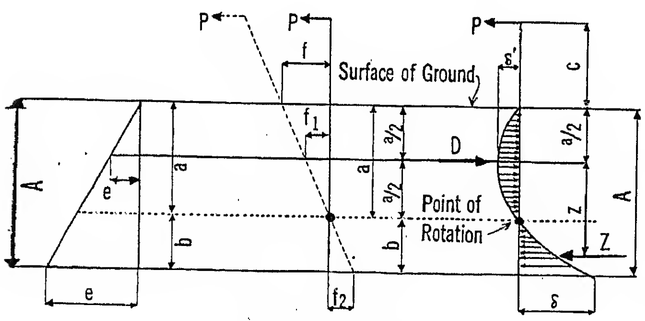
$$A = \frac{3P}{\delta d} + \sqrt{\frac{12PC}{\delta d}} = A_1 + A_2,\quad A_1 = \frac{3P}{\delta d}\quad A_2 = \sqrt{\frac{12PC}{\delta d}}$$

Earth pressure δ = 5000 lb./sq. ft.



NOMENCLATURE

a = distance from point of rotation to surface of ground.
b = distance from point of rotation to bottom of pier.
c = distance from surface of ground to point of application of overturning force.
P = overturning force on pier, or horizontal shear at surface of ground.
D = resisting force of earth above point of rotation
Z = resisting force of earth below point of rotation.
A = total depth of pier below surface of ground.
z = distance between centers of gravity of earth pressures above and below point of rotation.
δ' = maximum unit earth pressure above point of rotation.
δ = maximum unit earth pressure below point of rotation.
f = deflection of pier at surface of ground.
f_1 = deflection of pier at center of gravity of earth pressure above point of rotation.
f_2 = deflection of pier at bottom.
e = passive earth resistance at bottom of pier.
e' = passive earth resistance at center of gravity of earth pressure above point of rotation.
d = width or diameter of pier.

by reference to the chart shown in Fig. 5. In addition to the determination of the bearing pressure under the footing, these foundations were checked against overturning, using a factor of 1½.

In staking out the foundations for construction, two stakes were set on each center line and grade was referenced from the top of an adjacent tie. The concrete was poured from a mixing plant mounted on flat cars and handled in a work train. An inspector

†Wind on messenger and one-half wind on hangers assumed as acting at point of support of messenger, remaining wind on catenary system assumed as acting at steady wire.

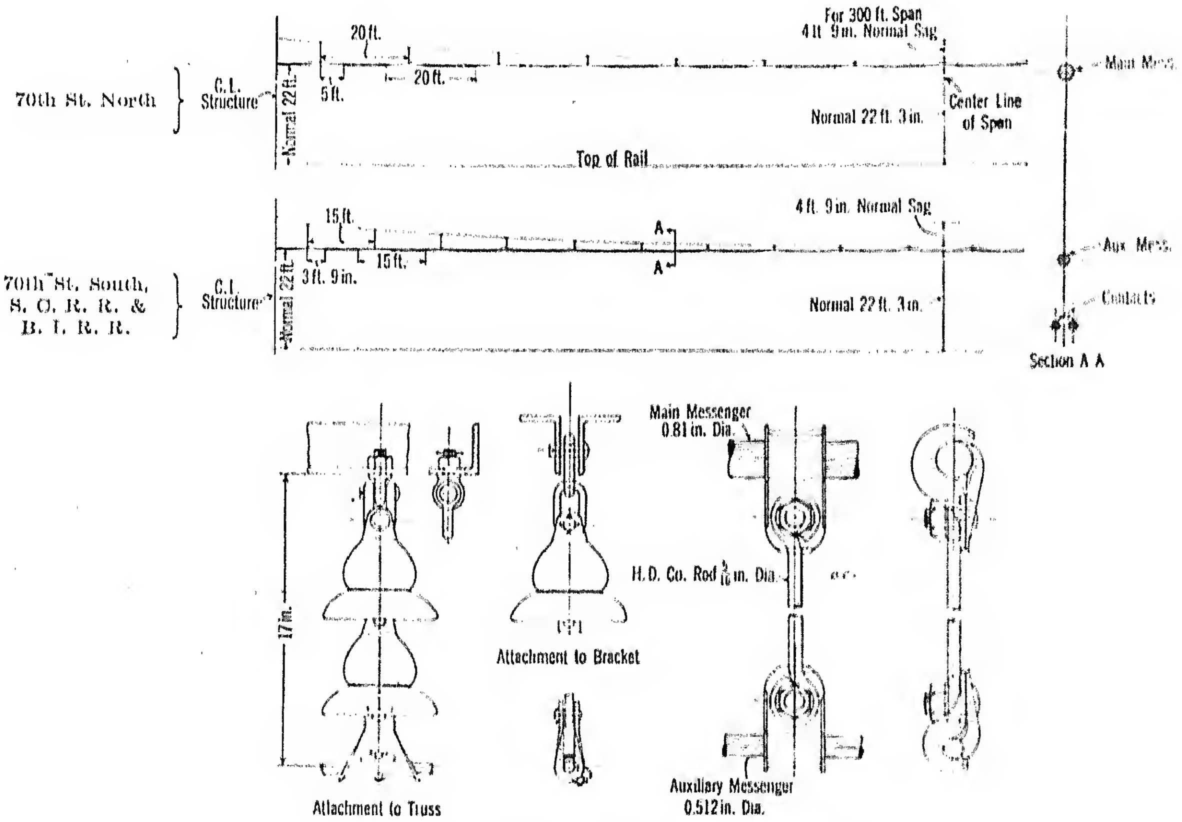

FIG. 8—MAIN LINE CATENARY SYSTEM

CATENARY STRUCTURES

The catenary structures for the suburban electrification were designed so as to permit extensions to include the remainder of the right-of-way. In some instances this means an ultimate structure of 200 ft. or more in length, made up of several spans. A reference to Fig. 1 will show the suburban catenary structures in heavy line, proposed extension to the east for through passenger and freight tracks, and further extensions to the east and west, shown in dotted lines, to include the entire right-of-way which at this point has a width of 250 ft. This provision necessitated calculations of the stresses in the complete structure and a check of the stresses in the initial structure. To reduce the labor and time required for such troublesome calculations, it was decided to adopt the Beggs method for

the mechanical determination of statically indeterminate stresses. This method proved very satisfactory and greatly facilitated the work. Fig. 6 shows an application of the Beggs apparatus to a five column structure.

The structures were erected, painted, and the base plates grouted by the railroad forces, very expeditiously and with little interruption to the regular traffic.

Catenary System

Table I shows the loadings of the catenary system and

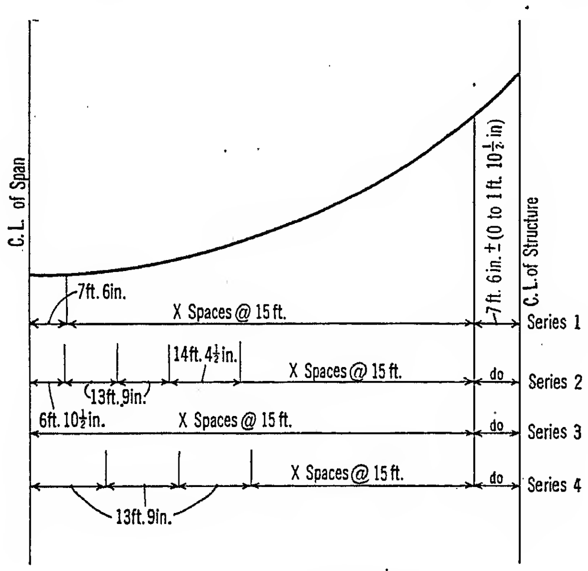

Fig. 9—Catenary Hanger Chart

Fig. 7 shows a very convenient and easily workable chart for a determination of the tensions and sags in the messenger for any assumed condition of temperature or loading. The curves shown on Fig. 12 were prepared from this chart.[2]

About the time when the make-up of the catenary system was being considered, the General Electric Company was carrying out some tests of double trolley wire construction at Erie, Pennsylvania. Illinois Central representatives were invited to witness some of these tests and were favorably impressed with the practically arcless collection of heavy current at high speed, and shortly the decision was reached to adopt the double trolley system. At the same time it was decided not to use parallel feeders but to equip each track with a catenary system of sufficient current-carrying capacity to keep the voltage drop within the prescribed limit, when normally in parallel with other tracks at sub- and tie-stations.

After these decisions were made it was a simple matter to select the main and auxiliary messengers to make up an adequate catenary system. Fig. 8 shows the main line catenary assembly. On the main line 4/0 copper trolley wires were used south of 70th Street and on the South Chicago Railroad and the Blue Island Railroad. Bronze trolley wires were selected for use north of 70th Street where the traffic is most dense. To compensate for the lower conductivity of the 3/0 bronze as com-

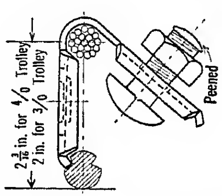

Fig. 10—Trolley Wire Clip

pared with the 4/0 copper trolley wires, the auxiliary messenger was increased in size. A 0.375-in. auxiliary was used with the 4/0 trolley and a 0.512-in. auxiliary with the 3/0 trolley.

The main messenger cable is of composite construction made up of seven Copperweld wires forming the core around which are stranded 12 hard-drawn copper wires. This cable is 0.81 in. in diameter and has an ultimate strength of 31,500 lb., which allows a sag of 4 ft., 9 in. in a 300-ft. span at 60 deg. fahr., giving a factor of safety of 2½ under the maximum assumed loading of the system.

The auxiliary messenger is made up of 19 strands of hard-drawn copper and has a normal tension of 800 lb. which gives a little sag between hangers and increases the flexibility of the trolley wire supporting structure.

The catenary hangers are simple, consisting of bronze

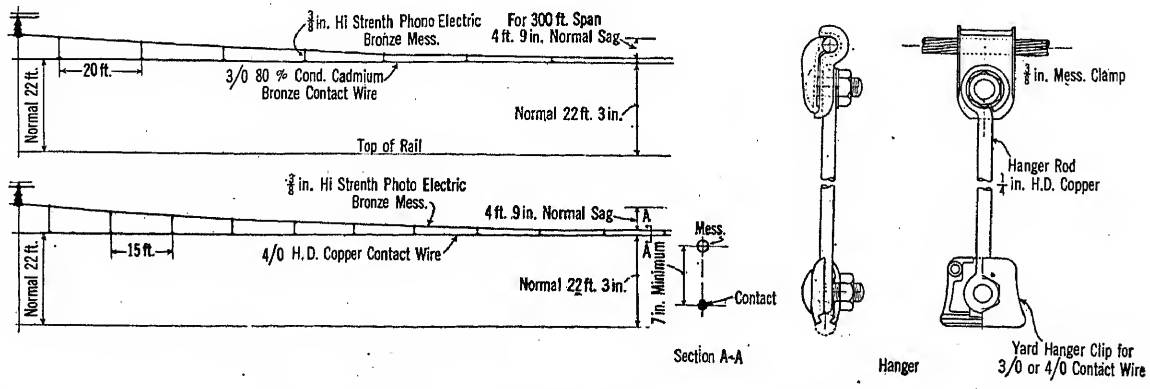

Fig. 11—Catenary Construction for Yards and Sidings

2. The method of constructing this chart was published in the A. E. R. A. *Proceedings* for 1925.

clamps for main and auxiliary messenger connected with a 5/16-in. diameter hard-drawn copper rod with an eye

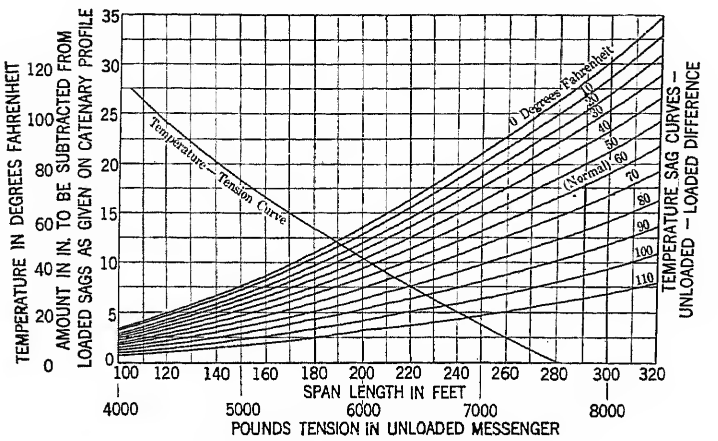

FIG. 12—TEMPERATURE—SAG CURVE

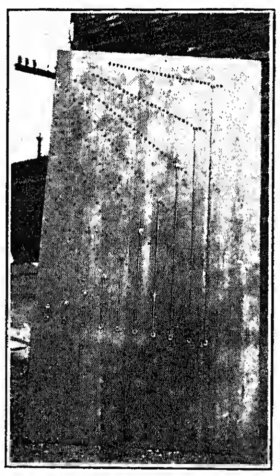

FIG. 13—HANGER BOARD WITH HALF SPAN OF HANGERS CUT TO LENGTH

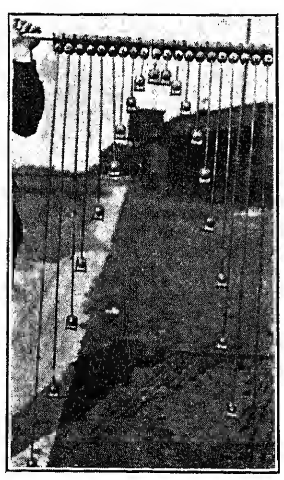

FIG. 14—COMPLETE SPAN OF HANGERS ASSEMBLED ON PIPE

in each end. To simplify the determination of the hanger lengths and to aid in the spacing of the hangers in the field, a diagram was prepared to divide the span lengths into four series. Fig. 9 shows the arrangement for the system having a normal hanger spacing of 15 ft. This diagram was laid out on a table-top to full vertical scale and to ¼ in. equaling one foot horizontal scale. The eye-to-eye lengths of the hangers were measured from points on the curve to a line representing the normal position of the eye of the hangers. In cases where the position, with reference to the messenger, of the trolley wires is other than normal, a straight edge was adjusted to represent this change and the hanger lengths measured to it. The clips between the auxiliary messenger and the trolley wire are unique in that they are formed of one piece of stock as shown in Fig. 10. The manufacturer delivered these clips with the T-head bolts and nuts assembled as shown.

Double insulation to ground was used throughout, the standard suspension unit being two seven-in-disk, 8000-lb., M. & E., cap and pin insulators attached to the

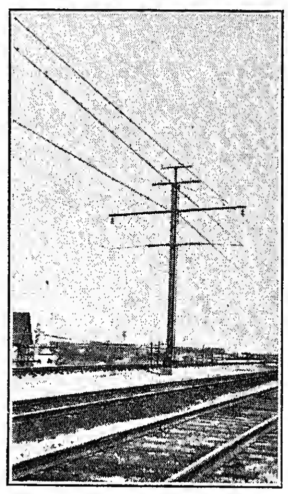

FIG. 15—TYPICAL 2-TRACK T BRACKET CONSTRUCTION

structure by means of either a galvanized eye-bolt-and-clevis or a double-link, depending upon the type of structure to which the attachment was made.

The suspension or saddle clamp is U-shaped to which the messenger is clamped by means of one J-bolt and keeper. Tests made on this clamp showed that the messenger would slip at an unbalanced tension of about 1000 lb. In the structure design, a broken wire load of 1000 lb. was allowed for. This broken wire load was figured for only one track per structure.

The fittings used for splicing and terminating the main messenger were developed after considerable experimenting and testing. These fittings consist of a combined chuck and poured socket so arranged that the the poured zinc button will follow against and keep tight the cone-shaped chuck. These fittings will develop the full rated strength of the composite messenger cable.

The seven-in-disk insulators used for suspension were also used in steady- and pull-off-strand construction to insulate from structure and to insulate separate sections.

For terminating the main line catenary system a very sturdy type of double strain insulator was used, one set for the main messenger and one set for the two trolley wires and auxiliary messenger combined.

The yard construction is shown on Fig. 11. Only a single trolley wire of either 3/0 or 4/0 gage was used. All yard catenary was supported from steel structures except Weldon Yard where some cross-span construction was used.

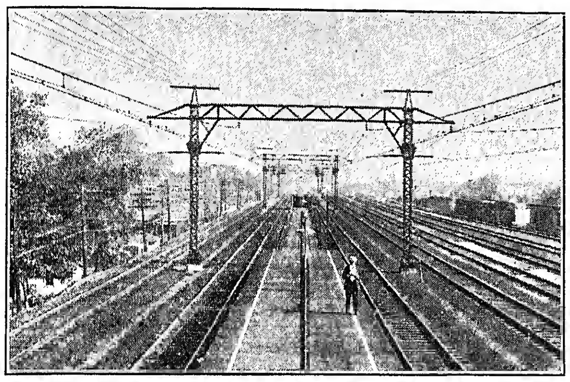

FIG. 16—TYPICAL 4-TRACK CONSTRUCTION

CATENARY CONSTRUCTION

All of the wires were strung and the remainder of the main line work practically completed from work trains. The yard work, except wire stringing, was completed from push-tower-car and ladders. The heavy equipment for construction consisted of reel cars with special shafts and brake rigging, tower cars with winch operated platforms adjustable from 15 ft., 6 in. to 19 ft., 6 in. above top of rail, and box cars fitted with work benches, shelves, and bins for tool cars.

The typical train for wire stringing consisted of a locomotive, reel car, tool car, and one or more tower cars. Only one main messenger was strung at a time, but the auxiliary messenger and the two trolley wires were strung together. The main messenger was tensioned by means of a sight rod and surveyor's level. The auxiliary messenger and trolley wires were tensioned with a dynamometer. These wires were all erected and tensioned in roller bearing rollers, the proper sag for the main messenger being determined from curves shown in Fig. 12.

The hanger chart described above was used in the material depot to check the length of the hangers as they were assembled on a piece of ½-in. pipe, three ft. long. After the hangers were assembled on the pipe, a linen tag was attached showing the location of the span and the series number of the hanger. See Figs. 13 and 14.

In erecting the hangers, the contractor used a steel tape, one side of which was marked in span lengths and the other marked with the recurring figures 1 to 4 inclusive, representing the four series of spacings. These figures were spaced as on the hanger board, but to full scale. This tape was stretched alongside the messenger, adjusted to the span, and the hangers were placed opposite the series figure.

MAINTENANCE

The maintenance of the catenary system is handled by the Maintenance of Way Department, using one 1-ton and one 1¼-ton motor trucks equipped with special bodies for hand tools, supplies, and ladders. These trucks are used for all light repair work as it is possible to approach the right-of-way in the electrified zone on paved or hard surface streets or roads. For heavy repair work two construction trains, each consisting of reel, tool, and tower car, are located at points on the terminal where a steam locomotive is readily available.

Soon after the start of the electric operation, trouble was experienced due to the pantographs striking the insulators which form part of the air-gap construction and either damaging the gap or so damaging the pantograph as to result in line trouble elsewhere. During the severe cold weather, some trouble was caused by failure of faulty fittings or by poor workmanship and to pantographs fouling the steady arms. The latter trouble was due to the fact that the trolley wires, at very low temperatures, lifted higher at the structures than was anticipated.

Main line construction was sectionalized by means of air-gaps, but wood section insulators were used in cross-overs where high speed is not attained. These insulators were originally equipped with two bronze gliders to give continuous feed. It was later found desirable, however, to install four gliders, two on each side of the wood stick to prevent the insulator rocking when the pantograph passed.

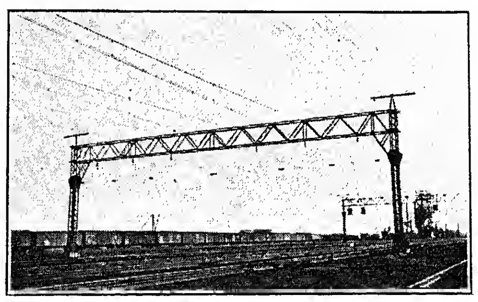

FIG. 17—TYPICAL 6-TRACK CONSTRUCTION

Occasionally the gliders of a wood section insulator will burn in two when a pantograph bridges a live and a grounded section, and on two occasions a trolley wire has burned in two at an air-gap due to the same cause.

The chief troubles were mentioned above and there have been minor failures but on the whole the operation has been highly satisfactory.

Discussion

For discussion of this paper see page 1133.

The Collection of Current From Overhead Contact Wires

BY R. E. WADE[1] and J. J. LINEBAUGH[1]
Non-Member Associate, A. I. E. E.

Synopsis.—Up to a few years ago, the generally accepted limitations for the amount of current which could be collected from an overhead distribution system were from 300 to 800 amperes in heavy interurban service and between 800 and 1000 amperes, with a maximum of 1500 in the case of the Chicago, Milwaukee, & St. Paul.

It is not possible to determine the limits of current collection by theoretical calculations nor by the experience on any particular installation. The tests described and analyzed in this paper were demonstrated on a four-mile track using special overhead construction of the twin trolley type with observation towers at several points to enable observers to carefully inspect commutation between the collector and the trolley wire.

Tests were also made to determine the temperature rise which would be obtained as a result of delivering, for a period of five minutes, a current of 5200 amperes to a standing locomotive. Further tests were made to determine what damage would result, if any, should a pantograph leave the wire while delivering currents as high as 4000 or 5000 amperes. Test data are included and description of the several types of overhead construction used.

Introduction

The problem of transferring current from overhead contact wires to moving cars and locomotives is one which cannot be solved by mathematics or laboratory tests. Neither can conclusions as to the limits of current collection be reached by experience on any particular installation.

There has been considerable discussion as to the amount of current that can be successfully collected from an overhead contact system. Except for standard railways, operating experience has been confined to the heavier types of interurban service, with current values of from 300 to 800 amperes, and heavy traction work such as the Chicago, Milwaukee, & St. Paul Railway, where normal current collected with single pantograph varies between 800 and 1000 amperes, with a maximum of about 1500.

Those who have made a study of the subject know that there is a large number of factors to be taken into account and that each of these factors is subject to considerable variation due to design, maintenance methods, or both; also that certain factors are essential for successful current collection on any given installation.

In view of the nature of the problem, as mentioned above, and the general interest in probable future requirements, a series of tests was conducted with the object of securing information as to the maximum amount of current that could be successfully collected from overhead contact wires with the conditions which are described later. These tests were made at Erie, Pennsylvania, on a section of track owned by the East Erie Commercial Railroad, and used by the General Electric Company for testing locomotives and cars. Following reconstruction of overhead contact system and completion of test runs, demonstrations of heavy current collection were given to engineers and railroad men on July 16, 17, and 18, and other dates, 1923.

These tests were planned and conducted in conjunction with the New York Central Railroad and the Cleveland Union Terminals Company.

It is thought that the importance of this subject, in connection with railway electrification work, justifies the compilation of a record covering the details of preliminary tests and investigations and the results as finally demonstrated.

Nature of Tests

Due to the fact that the capacity of the substation supplying power was limited to 6000 kw., tests were made at 850 and 1500 volts, using the lower voltage for the higher currents. Comparative collection tests were made at 850 and 1500 volts under identical conditions which clearly indicated that the voltage of contact line makes no difference in the collection of current so long as the voltage is more than adequate to maintain any arc that might occur between contact wire and pantograph.

Tests were also made to approximate conditions existing under prolonged acceleration periods, and to determine the temperature rise in various members of the contact system and in the collector.

With each change in contact wire arrangement and suspension, tests were started with low current values and at low speed and gradually worked up to maximum allowable values. A number of duplicate runs was made at maximum values to check the final results.

Testing Equipment

A. General. In order to make the tests contemplated, it was necessary to make certain changes in existing equipment and provide other equipment.

An attempt is made under the following headings to describe the various items of equipment provided and tried out, methods of making tests, the final type of overhead contact system selected for demonstration purposes, and the general conclusions reached following the tests and demonstrations.

B. Power Supply. Current was obtained from the substation used to supply power to the test track.

FIG. 1—SECTION OF TRACK USED FOR TESTS AND FINAL DATA ON CONSTRUCTION

The equipment consists of two synchronous motor-generator sets with switching arranged so that the generators could be used to supply any trolley potential from 600 to 3000 volts. One set with rating of 1000 kw. consists of two 500-kw., 1500/3000-volt generators direct-connected to a synchronous motor. The second unit is of similar construction consisting of two 750-kw., 1500/3000-volt generators. Full capacity could be obtained with series and parallel connections and lower voltages by adjusting the generator field rheostats.

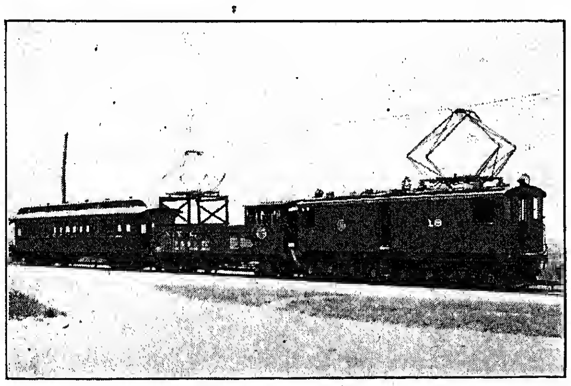

FIG. 2—TEST TRAIN CONSISTING OF LOCOMOTIVE No. 18, GONDOLA

With loading rheostats and observation car

Both sets are designed to carry three times normal load for five min. or a total of 6000 kw. This substation is located approximately 0.9 mi. from the west end and four mi. from east end of the track. Power was supplied to the overhead line through a 1,000,000-cir. mil feeder shown in Fig. 15.

C. Test Train. A special test train was assembled consisting of a 110-ton gearless locomotive capable of operating at speeds up to 70 mi. per hr. with either 600 or 1500 volts. This locomotive was coupled to a special gondola car followed by a standard passenger car used as an observation car equipped with ammeter, speedometer, and telephone, Figs. 2 and 3. These cars were furnished by the New York Central Railroad. As the weight of this train was not sufficient to give the current desired, a sufficient number of iron grid rheostats with contactors and switches arranged to give the

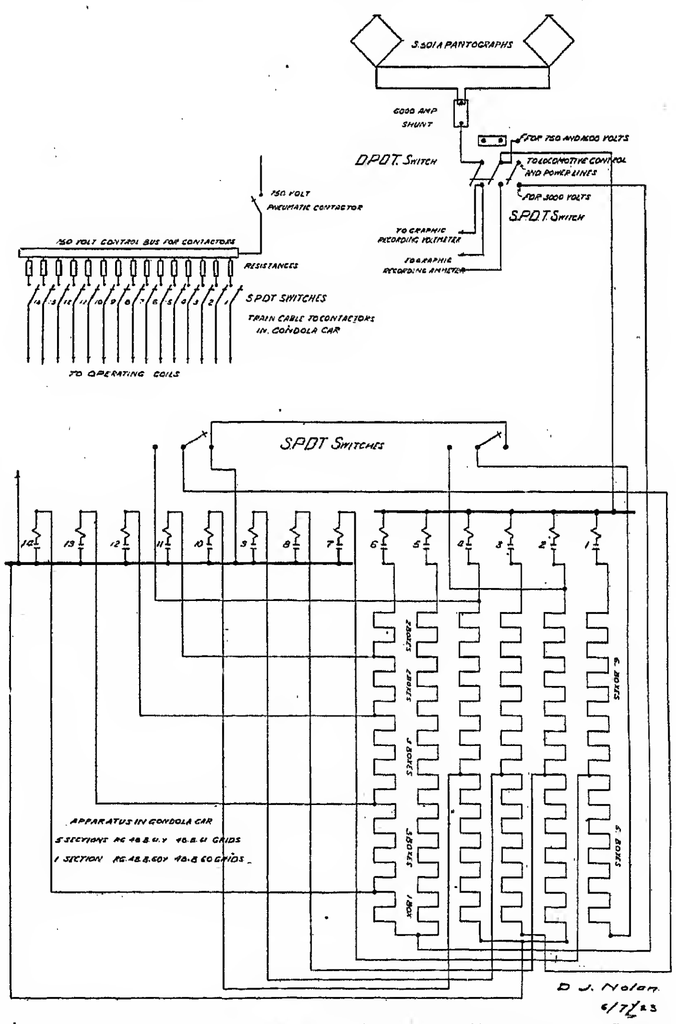

FIG. 3—WIRING DIAGRAM FOR CURRENT COLLECTION TESTS

Showing method of controlling current on test train consisting of Locomotive No. 18 and Gondola

additional current required for the tests was assembled in the gondola car. By means of this equipment, it was possible to obtain any load up to 6000 amperes at 850 volts and 4500 amperes at 1500 volts. It was also possible to obtain load at 3000 volts although only a few runs were made at this voltage. The two pantographs were installed 57 ft. apart which was considered representative spacing for a two-unit locomotive.

D. Track. The track used for general testing is 4.15 mi. in length and is laid with 100-lb. rail in slag ballast.

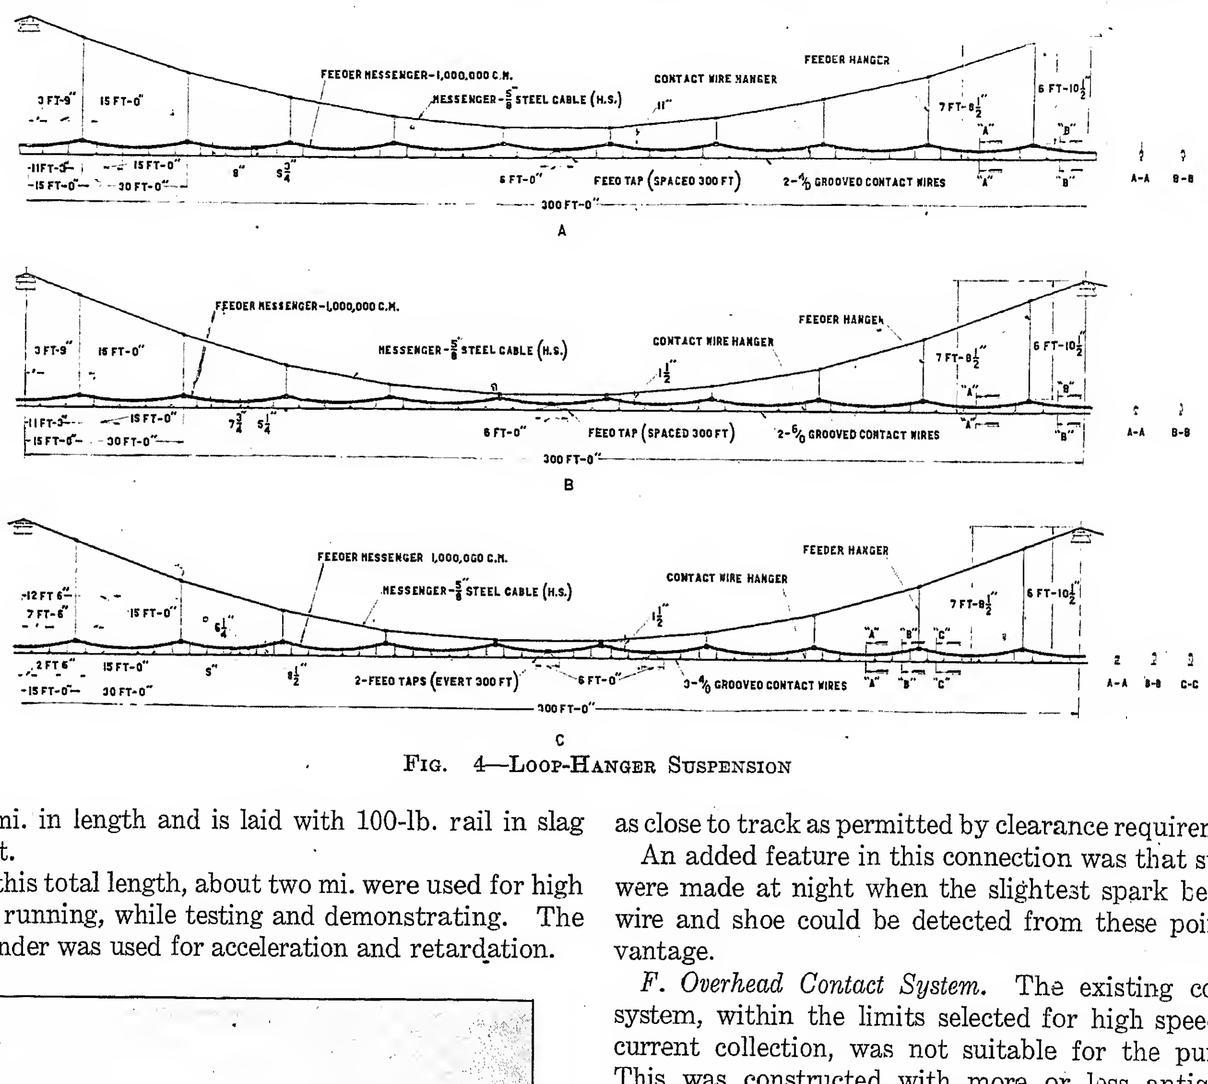

FIG. 4—LOOP-HANGER SUSPENSION

Of this total length, about two mi. were used for high speed running, while testing and demonstrating. The remainder was used for acceleration and retardation.

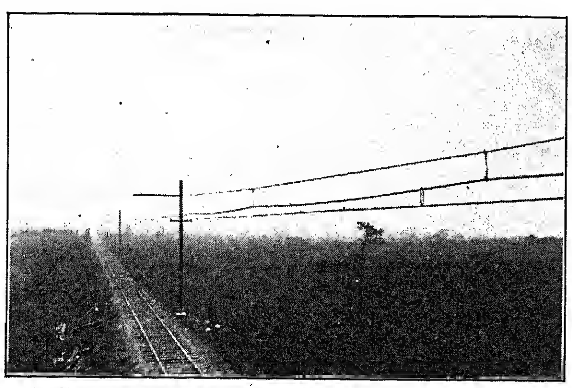

FIG. 5—LOOP-HANGER SUSPENSION WITH 2-4/0 CONTACT WIRES

Fig. 1 shows section of track used for high speed running and current collection.

E. Observation Towers. It was decided to make the unusual provision of observation towers in addition to the observation car referred to elsewhere.

There were five towers, located as shown on Fig. 1. The platform, capable of accommodating 12 to 15 people, is located at a height which places the eyes of the average observer slightly higher than contact wires and collector shoes, and provides an unobstructed view of all the parts entering into current collection, when approaching, passing, and leaving. Towers were located as close to track as permitted by clearance requirements.

An added feature in this connection was that studies were made at night when the slightest spark between wire and shoe could be detected from these points of vantage.

F. Overhead Contact System. The existing contact system, within the limits selected for high speed and current collection, was not suitable for the purpose. This was constructed with more or less antiquated fittings and was not in first-class condition.

In order to supply current for contemplated tests, a 1,000,000-cir. mil feeder was installed from a point about 620 ft. west of substation tap to a point about 3580 ft. east of tap. The old 750,000-cir. mil feeder was used for extension from the latter point to the east end of high speed territory, a distance of 5400 ft.

1. General Design of Contact System. On account of the heavy current values contemplated, it was thought advisable to shorten and simplify the taps between feeder and contact wires as much as possible, and to reconstruct with compound catenary, suspending the feeder from the messenger and the contact wires from this feeder messenger. With the length of span

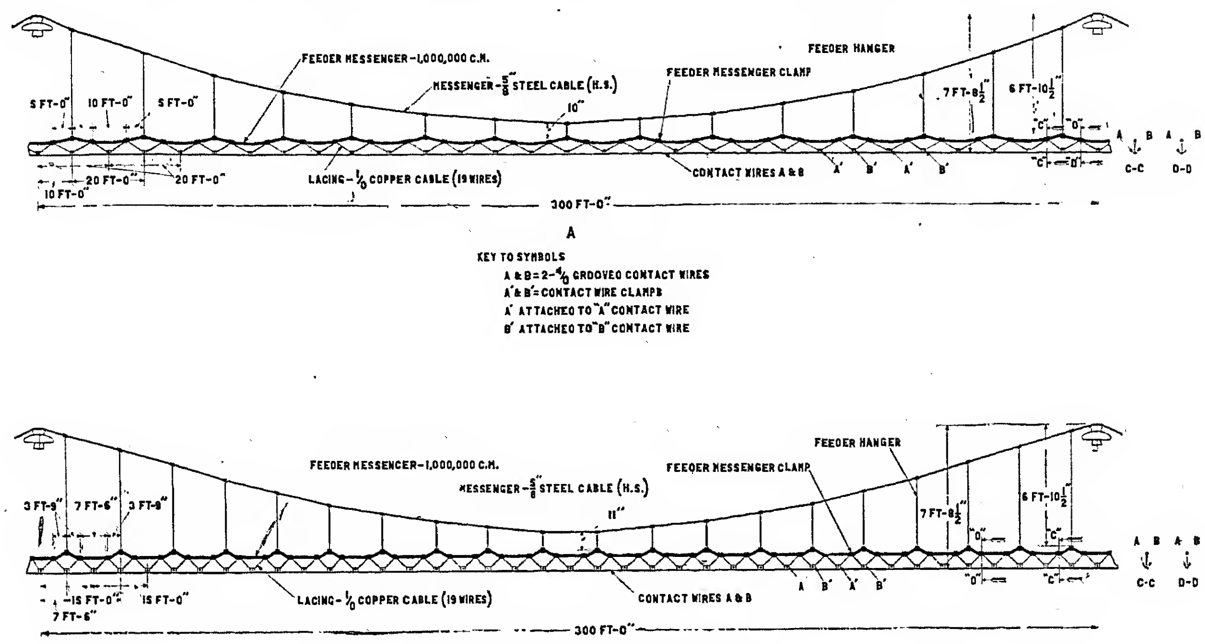

Fig. 6—Laced Suspension

adopted, 300 ft., ⅝-in. high-strength steel cable was selected for the messenger.

The feeder messenger was suspended from the messenger by means of hangers made of No. 2 A. W. G.

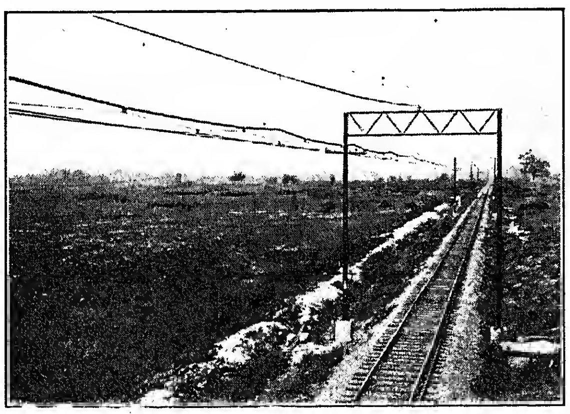

Fig. 7—Laced Suspension (Outside Rail for Testing Wide Gauge Locomotives)

solid, hard-drawn copper, with bronze clamps for attachment to messenger and feeder messenger.

2. Contact Wire Arrangements and Suspension. The first installation included several arrangements of contact wires and methods of suspension as described below, and referred to on Fig. 1. The table on this drawing gives the final arrangement.

a. Between points 1 and 2, 3600 ft. Two 4/0 wires, loop-hanger, suspension, (A), Fig. 4. Also Fig. 5.

b. Between points 2 and 3, 600 ft. Two 4/0 wires, laced suspension, (A) and (B), Fig. 6. Also Fig. 7.

c. Between points 3 and 4, 1200 ft. Two 6/0 wires, loop-hanger suspension, (B), Fig. 4.

d. Between points 4 and 5, 1200 ft. Three 4/0 wires, loop-hanger suspension, (C), Fig. 4. Also Fig. 8.

e. Between points 5 and 6, clamp suspension, 600 ft., (A) and (B), Fig. 9. Also Fig. 10.

f. Between points 6 and 7, 2400 ft. Two 4/0 wires, loop-hanger suspension, (A), Fig. 4. Also Fig. 5.

Short sections of two additional types of contact wire suspension were installed during preliminary tests.

g. Cable-hanger suspension, reproduction of photograph, Fig. 11.

h. Twin laced suspension with which the two contact

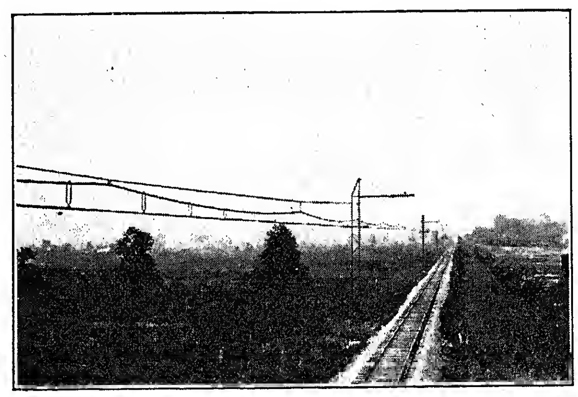

Fig. 8—Loop-Hanger Suspension With 2-4/0 Contact Wires

wires were suspended by independent lacings, from symmetrical yokes, attached to feeder messenger, locating them about 3½ in. apart and in the same horizontal plane.

3. Feed Taps. Loop-hanger suspension, (a) and (f), required feed tap connections, Fig. 12, which were installed at the center of each span or 300 ft. apart. Feed tap cable was 4/0 copper with 19 wires.

4. Reasons for Several Contact Wire Arrangements.

The selection of two contact wires, in the same horizontal plane, was due to previous experiments and actual experience on the Chicago, Milwaukee, & St. Paul Railway and other lines where current collected was of considerable value. The main virtue of this arrangement, in addition to the increased contact surface, is that with alternate or staggered suspension of the two wires, the collector shoe is always in contact with two wires, and one wire is always without any additional weight, due to hangers or other fittings.

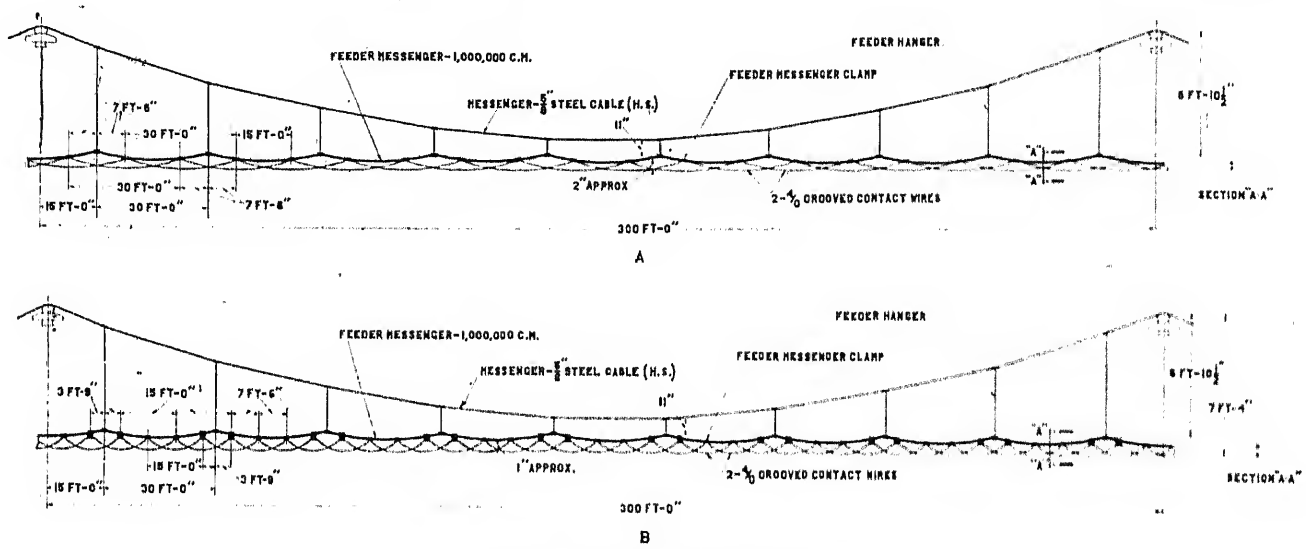

Fig. 9—Clamp Suspension

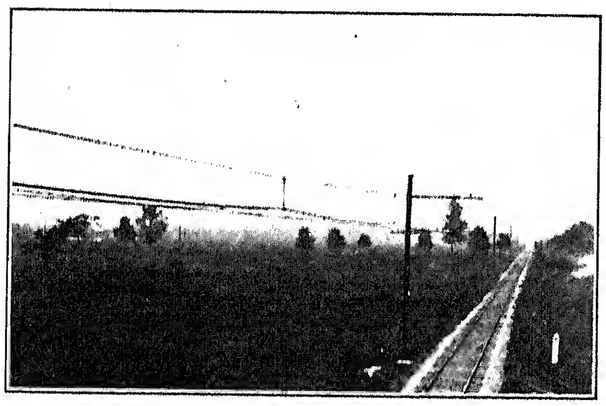

Fig. 10—Clamp Suspension

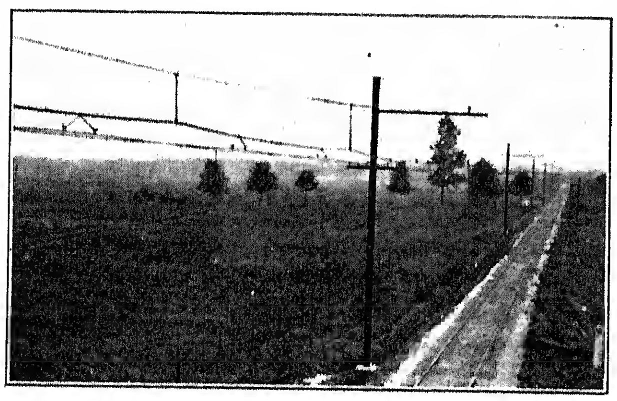

Fig. 11—Cable-Hanger Suspension

The installation of two 6/0 wires was made to get information as to the handling and performance of this size wire as a contact member: first, on account of its having been proposed by several foreign engineers; second, to try out this method of increasing cross-section should the two 4/0 wires show undesirable temperature rise; third, to study the effect of the additional weight in contact wires.

The installation of three 4/0 wires was made in line with possible need for more cross-section and more contact and to get experience in connection with their use, including the additional weight.

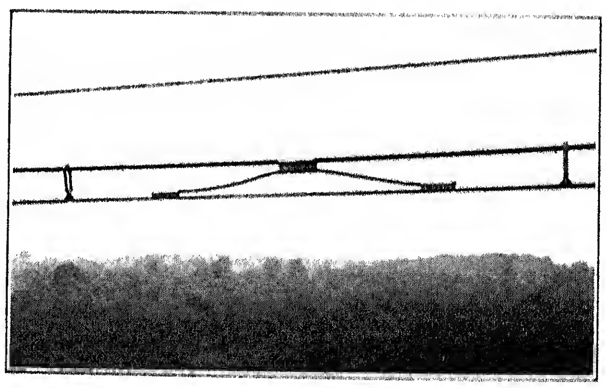

Fig. 12—Feed Tap With Loop-Hanger Suspension

Methods of Making Tests and Basis for Conclusions

With the several types of contact wire arrangement and suspension in place, for any given set of test runs, the remaining fixed factor was line voltage. Those subject to change were speed, amount of current collected, number of pantographs, and pantograph pressure.

Observation tower construction and location permitted direct comparison between the performance of the several types of overhead construction with a

certain line voltage and any desired combination of the variables.

Independent and simultaneous observations were made by four or five individuals from the same tower, and such observations made from several towers for each principal condition, so as to cover different types of construction and track alinement.

Satisfactory collection was fixed upon as being practically sparkless collection when so observed at night and when looking down on top of collector shoes.

Results of Experiments With Contact Wire Suspension

General. The original layout contemplated the general use of loop hanger suspension (a), (c), (d), and (f), and the short section of clamp suspension (e). During the early stages of the test runs, short sections of laced suspension (b) and cable hanger suspension (g) were installed and compared with loop hanger and clamp suspension, with the results given below.

1. Loop Hangers (a) and (f). This type of suspension was selected for the larger portion of the work on account of flexibility and because it was being successfully used when currents of considerable magnitude were encountered, in regular service, though smaller in value than the heavy currents contemplated in this case.

With the general construction used for these tests, loop hangers, with feed taps spaced 300 ft. apart, provided the necessary conductivity between feeder messenger and contact wires for current values not in excess of 2500 amperes.

The Chicago, Milwaukee, & St. Paul Railway, using simple catenary construction, with loop hangers, steel messenger, and two 4/0 A. W. G. copper contact wires in the same horizontal plane, during an operating period of 11 years, and a total of 650 route mi., has had about three interruptions on account of messenger being burned at loop hangers.

These cases were all due to defective feed tap clamps at contact wire shunting the current through the steel messenger. General replacement of these clamps was made with an improved design and no further trouble of this kind has been experienced. Other roads equipped with the improved clamp have not experienced this trouble.

2. Laced Suspension (b). This method of suspension offered flexibility in line with that of loop hangers and the added feature of very frequent taps to feeder messenger and cross taps between contact wires. The first trial was made with two feeder hanger spacings, 30 ft. and 15 ft., with a minimum distance of six in. between top of contact wires and under side of feeder messenger. A few test runs indicated that the section with shorter hanger spacing gave better collection. Comparison with other types of suspension tested brought about the conclusion that the laced suspension provided the best conductivity between feeder and contact wires for the collection of the amount of current contemplated, and it was therefore adopted for further test runs and demonstrations.

3. Clamp Suspension (e). This design possessed the following features: Direct connection between contact wires and feeder messenger, the use of clamps instead of more expensive hangers or clamps and lacing, and the possibility of operating contact wires at comparatively low tension. After a few test runs this design was dismissed from further consideration for the purpose in hand. With two contact wires the lift was such that pantograph shoes struck feeder messenger clamps. While an increase in number of wires would tend to reduce the lift, the complication accompanying additional wires and the fact that one shoe would, with any number of wires, make contact with one wire only, throughout a great part of the line, did not encourage further investigation at that time.

4. Cable Hanger Suspension (g). About 150 ft. of line was equipped with these hangers, spaced 15 ft. apart, or 30 ft. on each contact wire. For test purposes, hangers were made of 1/0 B & S flexible copper strand, and the contact wire clamps used with laced suspension. Attachment to feeder messenger was made by copper wire wrapping.

This suspension approached laced construction in general principle and provided a manufactured unit, permitting attachment of clamps to strand by welding or other means supposedly preferable to clamped connection. This suspension showed no improvement over the simpler laced construction and the design was therefore eliminated.

5. Twin Laced Suspension (h). The trial of this suspension, incidental to collection trouble with laced suspension on a one-deg. curve, was made during the early stages of the tests. The design was never given serious consideration on account of inherent faults, including expense of two lacings, the special yokes for attachment to feeder messenger which would be expensive and difficult to maintain in any desired plane.

Results of Experiments with Contact Wire Arrangements

Shortly before the completion of test runs and the demonstrations of current collection, it was decided that two 4/0 contact wires in the same horizontal plane with proper suspension and tension provided the necessary cross-section, contact surface, and weight for current collection covered by the tests.

While the experience gained with 6/0 contact wire was limited to a very small quantity, the condition of the wire, as installed, was never satisfactory owing to long kinks, presumably due to winding on reel. While this trouble may be avoided by using a reel with proper drum diameter, the general impression was that wire of this size should be passed through a wire straightener, mounted on tower car, as it is strung. As stated above, there seems to be no reason for adopting this special and undesirable size of wire.

While no particular trouble was encountered in connection with the three 4/0 contact wires, there was no indication of the additional wire being required, and its use would certainly complicate the contact system and introduce the undesirable requirement of maintaining approximately even tension in three wires instead of two in order to get the best results.

The following data apply to contact system finally used for tests and demonstrations:

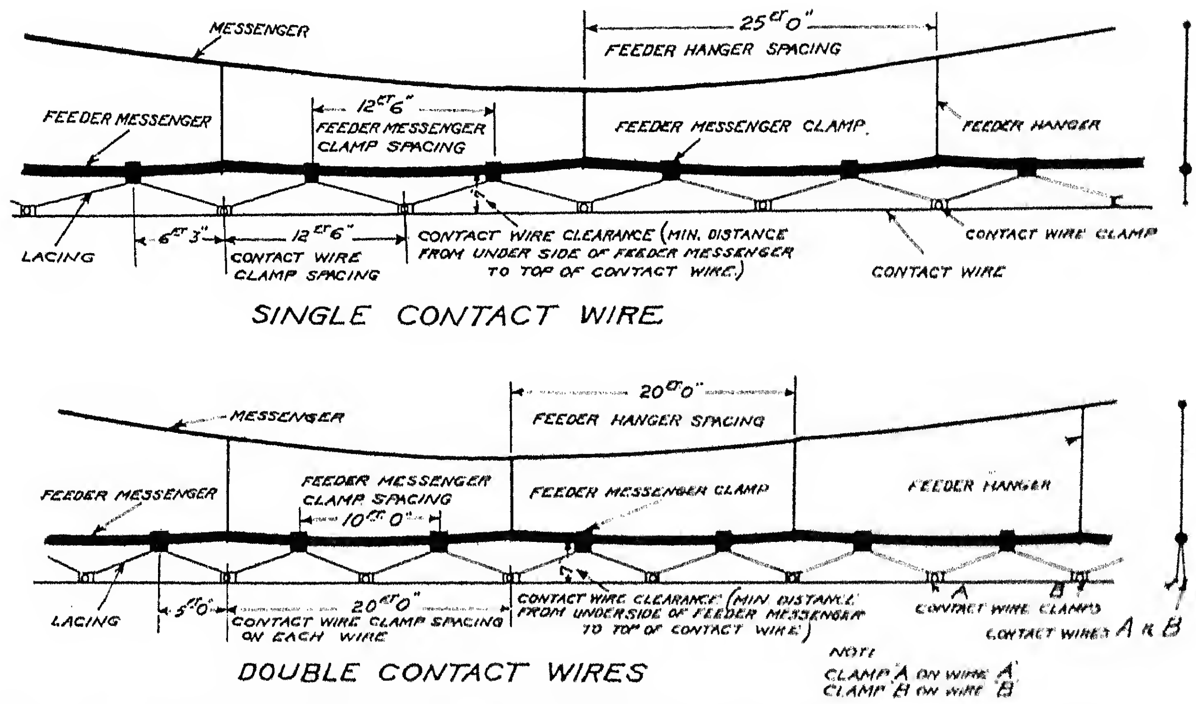

FIG. 13—CATENARY CONSTRUCTION LACED SUSPENSION FOR CONTACT WIRES (FINAL RECOMMENDATIONS)

Member	Material	Size	Wt. lb. ft. pounds
Messenger................	H. S. Steel	5/8 in.	0.8
Feeder Messenger........	Copper	1,000,000 cir. mils	3.1
Feeder Messenger........	Copper	750,000 " "	2.325
Lacing....................	Copper	105,000 " "	0.322
Contact wire 1...........	Copper	211,600 " "	0.64
Contact wire 2...........	Copper	211,600 " "	0.64

After completion of tests it was decided that the arrangement with laced suspension for single and double contact wires should be as shown on Fig. 13.

CONTACT SYSTEM ON CURVES

All curve work in the original installation was fitted with loop hanger suspension for contact wires, and both feeder and contact wire hangers were inclined, as shown in Fig. 14. This illustration also shows feeder connection at substation, consisting of one 1,000,000-cir. mil. cable, which supplied current to line for all tests including heat runs.

Current collection on this curve construction, as experimentally installed, in combination with other factors affecting current collection, was not satisfactory on account of arcing. Laced suspension with inclined messenger gave the same results. No further studies were made with inclined hangers but contact system was trimmed in chords with pull-offs located 150 ft. apart, as shown in Fig. 15.

The final combination of laced and chord construction gave practically sparkless current collection.

CONTACT WIRE TENSION

As originally installed, contact wires had a tension

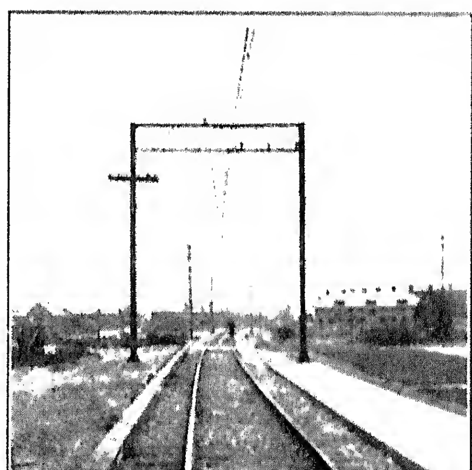

FIG. 14—LOOP-HANGER SUSPENSION ON CURVE
Showing inclined messenger construction

of 1000 lb. at 70 deg. fahr. Before tests were completed, this tension was considerably below that value due to seasonal increase in temperature and many changes made in line construction. When curve work

was finally adjusted, late in June, tension was increased to from 1300 lb. to 1400 lb. at 70 deg. fahr. and with improved collection throughout.

Collectors

The collector used throughout for test runs and demonstrations was the S-501-A slider trolley, with certain modifications mentioned later, Fig. 16.

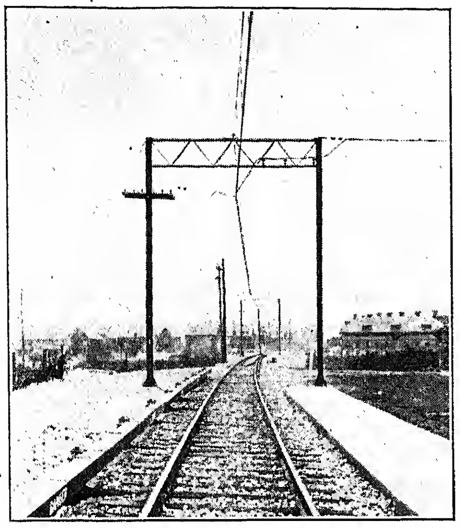

Fig. 15—Laced-Type Suspension on Curve

Showing chord construction and feeder connection

The collector consists of two flexibly mounted, contact shoes on top of a jointed diamond or pantograph frame, the diamond or pantograph frame being constructed of Shelby tubing with malleable iron joint castings so hinged together that it can readily expand or contract to suit variations in height of contact wires.

The collector is expanded or raised to its operating position by means of four large coil springs attached to cams mounted on the same hinge shaft as the bottom part of the diamond frame. Two of the large springs are energized and permanently attached to the base of the collector for balancing approximately the dead load of the moving parts. The other two large springs are connected to air cylinders by means of which they can be energized or de-energized at will.

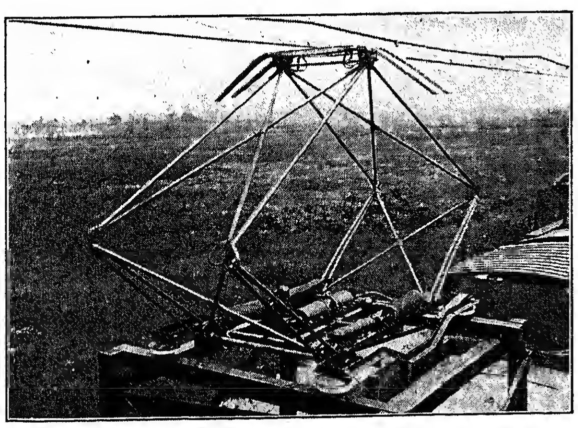

Fig. 16—S-501-A Pantograph Used for Current Collection Tests

As mounted on wooden structure in the Gondola carrying the grids

The small irregularities in the overhead are taken care of by the flexibility of the contact shoes. Each shoe is independently hinged on two spring supported cams which allow it to rise and lower two in. independent of the main or diamond frame. The contact shoes are composed of sheet steel pans with sheet steel horns attached to each end for picking up the siding wires. The wearing strips are of hard drawn copper, 3/16 in. thick and 1-3/16 in. wide, having one edge bent over slightly to prevent fouling, leaving approximately ¾ in. of width, flat surface. On each side of each pan is one long, renewable, wearing strip, and in the middle of each pan where most of the wear is concentrated between the outside strips, two short, renewable, wearing strips. This gives at the middle section of each shoe a line contact with the contact wires of approximately three in. or a total for both shoes of six in. The space between the renewable, wearing strips is filled with a lubricant for preventing a rapid deterioration of both strips and contact wire. Shoes are shown in plan in Fig. 17.

The standard collector has a rated continuous capacity of 1000 amperes, or 2000 amperes for two min., and is suitable for speeds up to 60 mi. per hr.

In order to bring the capacity up to the heavy current requirements, the collectors were fitted with additional shunts around each bearing and a flat copper strip along one side of both top and bottom frame arms. The additional weight imposed by this copper necessitated increasing capacity of balancing springs.

As far as principle of design goes, a standard collector was used and the only special precaution taken was to surface the wearing strips on an emery-covered face plate after assembly, which should be done in regular practise regardless of current values.

Collector Pressure

During testing period, collector pressures varying between 19 and 43 lb. were used. Reference to list of test runs shows that the pressure finally used for the collector and contact system dealt with was about 40 lb. This pressure was necessary on account of the increased moving weight due to copper shunts and strips.

Current Collection Tests

The following list gives data on a group of representative test runs with both 850 and 1500 volts, using the type of contact system finally adopted. More than 350 test runs were made and records kept in connection with all runs.

Temperature Tests

Temperature tests were made to determine heating of the contact wire, feeder, messenger, pantograph shoe, etc., in order to definitely establish that it is possible to conduct heavy currents to a locomotive. These tests were made on the laced overhead trolley construction as shown in Fig. 7. The feeder in this section is a 1,000,000-cir. mil copper conductor acting as a messenger.

The general arrangement of the test train, location of pantographs, and overhead construction is shown in Fig. 18. The thermometers were placed on the contact wire, feeder, lacing, and messenger near lacings, 1, 4, 10, 13, 23, 30, and 32.

Test No. 1: This test was made with both pantographs raised and current maintained at approximately 5200 amperes for five min. Nine readings were taken at one-min. intervals, the first five being taken while current was flowing and the last four after the circuit was interrupted. A maximum temperature rise of 67 deg. cent. was obtained on the contact wire near pantograph 2, lacing 23.

Test No. 2: This test was made with one pantograph located near lacing 23 with approximately 5200 amperes for five min. Ten readings were taken, five while current was flowing and five after interruption of the circuit. A maximum temperature rise of 101 deg. cent. was obtained on the contact wire near the pantograph.

These tests do not reproduce exact operating conditions after a train has started but might apply while locomotive is standing still, attempting to start a train. The temperatures obtained are so low and the current and time used in the tests so high that they clearly indicate that no trouble would be experienced due to overheating of the distributing, contact, or collecting equipment.

Burn-Off Tests

These tests were made to determine the amount of burning which would be obtained if a pantograph should start to drop while carrying heavy currents and for some reason was checked and held in position a few inches from the contact wire. These tests were made with the locomotive standing still. While different amounts of current were passing through the contact wire and pantograph, the pantograph was released, stopped, and held. Potential of 1500 volts was held on the contact wire throughout the tests. Twenty tests of this kind were made, with current reaching a maximum of 4400 amperes, the maximum drop of the pantograph being 17 in. and the minimum one in. In no case was the contact wire or pantograph seriously damaged. A pantograph was also dropped without checking, with 5000 amperes, at 850 volts, without serious damage.

Several tests were made interrupting 4000 amperes at 1500 volts with locomotive control arranged so that if the pantograph should begin to drop due to low-air pressure, a pressure relay on the locomotive would open the main breaker and interrupt the circuit. With this system of control, there was no sparking at pantographs.

Conclusions

Contact System Design. Contact systems, in actual use, for heavy traction, vary in principle of design between direct suspension, with considerable weight concentrated at points of contact wire support, and

catenary suspension, with practically no change in contact wire weight and freedom of vertical movement throughout. There is a corresponding variation in current transfer capacity.

It is desirable to provide a contact member of uniform flexibility and, as far as possible, of uniform weight throughout. The necessity for flexibility and uniformity in weight increases as current values increase.

It is important to avoid the use of fittings which obstruct in any way the contact between contact wire and pantograph shoes.

Contact Wire Lubrication. Experience gained by these tests and on lines equipped with the same or similar type of pantograph shows that a very thin film of lubricant should be maintained on under side of contact wire and that there is no difficulty in this connection provided pantograph shoes are properly lubricated.

It is interesting to note that contact resistance between wire and shoe is decreased when lubricant is used. This is probably due to elimination of chattering and actual glazing of contact wire and wearing strips of pantograph shoes.

Contact Wire Tension. Contact wire tension should be maintained at the highest value consistent with temperature conditions and other limiting features.

Current Collector Design. The efficiency of this device is affected by the following details:

Weight of moving parts and friction in bearings and joints which may interfere with its response to any change in contact wire height,

Design of contact shoe, including number and assembly of wearing strips, lubrication, and facilities for lubrication,

When two shoes are used, the degree of independence of movement and spring control,

The rigidity of pantograph frame in connection with side sway,

It is to be noted that a collector of standard design, with slight modifications to increase current carrying capacity, was used throughout these tests.

Shoe Pressure. The word "pressure" is intended to mean the pressure exerted at standard contact wire height with pantograph in motion or with friction practically eliminated. This value can be obtained by tying pantograph with shoe at standard contact wire height and reading pressure with spring balance while pantograph is shaken, thus approximating the condition while collecting.

It is desirable to emphasize the importance of pressure in connection with current collection, and, when more than one collector is used, the equalization of pressure.

Shoe pressure must be adapted to the overhead contact system design and should be maintained at the minimum value found practicable in each case.

Number of Collectors Used and their Spacing. These items determine the total upward pressure on contact wires and distribution of pressure, and certain combinations may disqualify a contact system suitable for use with a single collector or other combinations.

The number of collectors used must be determined by their design, current to be collected, and their minimum spacing, by overhead contact system design outside of locomotive design, and other considerations. It is desirable to make this distance a maximum.

Speed. The speed at which a collector is moved introduces the effects of wind pressure on pantograph frame and certain parts, such as shoe horns, the inertia of pantograph frame and shoes, and side whipping with bad track surface. It also places limits on grades in contact wire and changes in weight and flexibility of contact wire.

Effect of Voltage on Current Collection. Test runs were made with 750, 850, and 1500 volts. With all other conditions the same, no difference could be detected in quality of current collection with the three voltages mentioned.

General. Conservative evaluation of these tests and experience gained from operated lines indicate that 2000 amperes or more can be successfully collected, at any speed up to 60 or 70 mi. per hour, with one pantograph, and 4000 amperes with two pantographs.

These tests also demonstrate that it is practicable to design and construct an overhead contact and distribution system capable of delivering more than the amount of current required for train propulsion, with line potentials used to date for trunk line electrification.

The type of suspension, connecting messenger or feeder messenger and contact wire or wires, and its conductivity must be governed by the maximum current to be collected.

These tests and experience lead to the following approximate ratings for the types of construction given:

a. Steel messenger, two 4/0 copper contact wires, loop hangers, feed taps spaced 1000 ft., as used on Chicago, Milwaukee, & St. Paul Railway:

Normal current, 1000 amperes with a maximum of 1500.

b. Compound catenary with auxiliary feeder, messenger, loop hangers, and feed taps spaced 300 ft.

Normal current 2000 amperes with a maximum of 2700.

c. For higher current value, the frequencies of feeder taps must be increased in proportion to the current demand.

Discussion

For discussion of this paper see page 1133.

Railway Inclined Catenary Standardized Design

BY O. M. JORSTAD[1]

Associate, A. I. E. E.

Synopsis.—A description is given of a new method of overhead contact design, the "ideal inclined catenary." This is based on an originally discovered tension and weight relation formula. A proof of the formula is given and other characteristics of the design are mathematically analyzed.

A number of railroads now using inclined catenary is listed and data on the weights and tensions of their overhead constructions are given for comparison purposes with the "ideal."

The necessity of making a definite selection of a proper contact wire tension in any inclined catenary design is indicated and that this, together with the use of the design formula, leads to standardization of overhead systems is pointed out.

A RAILROAD track alinement is made up of a succession of tangents and curves. The overhead contact system in an electrification must be designed to follow the alinement so that the current collector of the car or locomotive will always make contact in a satisfactory manner.

Many types of overhead contact systems have been designed and applied on the many electrified railroads throughout the world. On tangent sections they are practically all similar in one respect, *i. e.*, their catenary hangers are vertical. The curve constructions, however, generally speaking, may be divided into two classes, one with hangers vertical as on tangent and the other with hangers inclined across the track. The vertical hanger type is called, by some, the polyhedral type and by others the chord type, as the catenary construction is pulled into a series of straight lines or chords over the track by pull-offs from a back-bone or pull-off posts. The inclined hanger type pulls the contact wire into a position over the curved track by inclining the hangers and thus causing them to function as combined pull-offs and hangers. Back-bones and pull-offs, except on the sharper curves, are usually omitted in the inclined catenary construction.

Chord construction is an adaptation of tangent construction to curves. Likewise, the more usual inclined construction has heretofore been the result of displacing the messenger of the correlated tangent construction laterally. In the United States, both types are in general use with inclined catenary the most common on main line electrifications. In other countries, however, the chord type has been the most favored. The following is a partial list of users of inclined catenary in this and other countries:

The New York, New Haven, and Hartford Railroad Co.

New York, Westchester, and Boston Ry.,

Boston and Maine Railroad.

Pennsylvania Railroad,

Norfolk and Western Ry.,

Virginian Ry.,

Detroit, Toledo, and Ironton Railroad.

Chicago, North Shore, and Milwaukee Railroad Co.,

Canadian National Rys.,

Lancaster, Morecambe, and Heysham Railroad in England,

Midi Railroad in France.

This list indicates that the inclined catenary is a practicable construction and that in every electrification of the immediate future it will in all probability come up for consideration. It also strongly indicates that an inclined catenary of some description will be a future standard overhead.

The good qualities of the inclined construction may be partially summarized as follows: It is artistic and makes a strong appeal to the esthetic sense. It is economical of material in that it employs two wire members to do the work of the usual three or four in the chord type. It has inherent automatic tension characteristics and above all it supplies a contact line that approaches most closely the ideal desired, *i. e.*, uniform flexibility. The greatest obstacle in the way of its more general use has been the comparative complexity of methods of design.

As stated above, the present forms of inclined catenary curve construction were developed from the correlated tangent construction and consequently acquired similar tensions and sags for similar lengths of spans. In the design of the tangent construction, there has been no fixed rule for determining the relative values of the various factors of design, tension, weight, sag, etc., of messenger and contact. The object sought was a maximum span with sags selected to keep the contact wire from being displaced by wind and leaving the collector. Such requirements resulted in a great variety of tangent catenary designs, each one depending on local and special conditions. The resulting related inclined catenary curve constructions were not entirely satisfactory from the designer's standpoint as there was difficulty in securing proper alinements but they were made operative and were usually a great improvement over previous chord constructions, particularly on multitrack sections.

There is now available, however, the discovered formula,

$$T_m/T_c = W_m/W_c \qquad (1)$$

which provides a basis for a simplified and precise design of inclined catenary. In the formula, W_c =

1. General Engineering Dept., Westinghouse Elec. & Mfg. Company, East Pittsburgh, Pa.

Presented at the Summer Convention of the A. I. E. E., Detroit, Mich., June 20-24, 1927.

weight of contact wire in lb. (kg.) per linear ft., T_c = tension of contact wire in lb., W_m = weight of messenger wire in lb. (kg.) per linear ft., and T_m = tension of messenger wire in lb. In this design, the contact wire is practically parallel to the center line of track and all hangers in any given curve are parallel, *i. e.*, they make the same angle with the vertical. Also it must be noted that it is the combination of the weight and tension relation indicated by the formula and the approximate parallelism of contact wire with center line of the curved track that provides what may be called an ideal inclined catenary. With one of the two conditions absent, an ideal inclined catenary is not secured.

It should also be noted that this ideal combination of conditions can be secured only at some one selected design temperature. A change in temperature tends to modify both of the combination factors in a construction, as T_c/T_m does not usually stay constant over a range of temperature and the contact wire distorts either vertically or horizontally with the least change in temperature. This variation of tension with temperature is, however, a characteristic of all non-automatic catenary constructions.

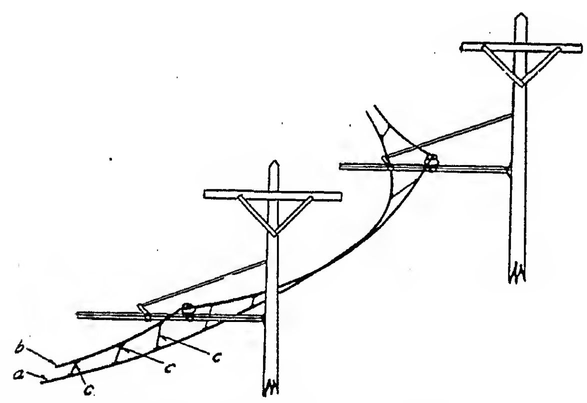

FIG. 1—SHOWING INCLINED CATENARY IN PERSPECTIVE

Also, any loss in weight of the contact wire after construction due to wear by collector causes a departure from the ideal design conditions. The loss in weight of contact is accompanied by a corresponding loss in tension and thus the formula is apparently satisfied. The loss in weight of contact wire, however, causes the tension of messenger to decrease due to its decreased load. This causes the messenger to rise, pulling up the contact wire at the middle of span with consequent distortion from its original position of parallelism to center line of track. Distortion due to loss of weight with wear, however, is common to all contact systems.

A demonstration of the truth of the formula may be made as follows. Fig. 1 is a sketch in perspective of the usual inclined catenary. Here *a* is the contact wire, *b* the messenger, and *c*, *c*, the inclined hangers. Fig. 2 is a plan view of an ideal inclined catenary span with zero length of shortest hangers. The contact wire *a* is a parabola and the curve *f*, the projection of the messenger on the horizontal plane of contact wire, is also a parabola.[2] The two parabolas are tangent at their vertices.

The ideal contact line or wire is defined as the wire under tension which lies in a horizontal plane and has the form of a parabola whose horizontal sag for a given span and curve is equal to the middle ordinate of the circular arc of the same span. For the usual spans and usual degrees of curvature there is practically no difference in the tensions or positions of the wire in the form of a parabola or an arc of a circle[3].

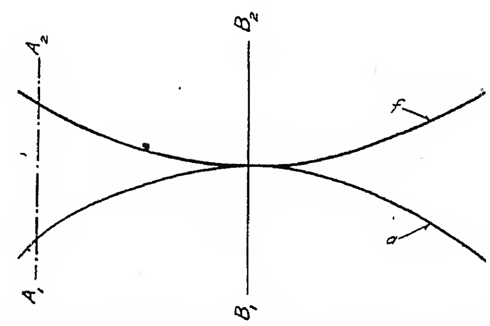

FIG. 2—PLAN VIEW OF IDEAL INCLINED CATENARY CONSTRUCTION

$A_1 - A_2$ Fig. 2 is a vertical plane through the messenger and contact parallel to the principal axis $B_1 B_2$ of the contact parabola. In Fig. 3 the triangle $g\ h\ i$ is a projection horizontally on the vertical plane $A_1 - A_2$ of Fig. 2 of the inclined catenary construction.

In Fig. 3:

$g\ h$ = horizontal sag of contact parabola,
$g\ i$ = hanger in the plane of projection,
$h\ i$ = sag of messenger.

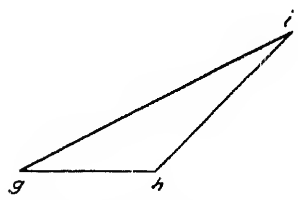

FIG. 3—PROJECTION HORIZONTALLY OF IDEAL INCLINED CATENARY CONSTRUCTION ON VERTICAL PLANE $A_1 A_2$ OF FIG. 2

Fig. 4 is a projection similar to Fig. 3 but with the following additional construction:

$g\ h$ is extended horizontally to o,
$i\ o$ is dropped vertically from i to o,
a vertical is constructed through g,
$i\ m$ is extended horizontally from i to meet vertical at m,
the diagonal $i\ h$ is extended to meet vertical at k.

In the triangle $m\ i\ g$ of Fig. 4, $i\ g$ has the slope of the hanger and if its length is assumed to represent the

2. See Appendix I.
3. See Appendix IV.

force on the hanger due to the dead load of contact wire and horizontal load caused by tension in contact wire then the latter two forces are represented respectively by the other two sides of the force triangle $m\ g$ and $m\ i$.

Likewise in triangle $m\ i\ k$ of Fig. 4, $i\ k$ has the slope of the messenger and as $m\ i$ represents the horizontal load on the messenger due to tension in contact, the other two sides of the triangle will represent the other

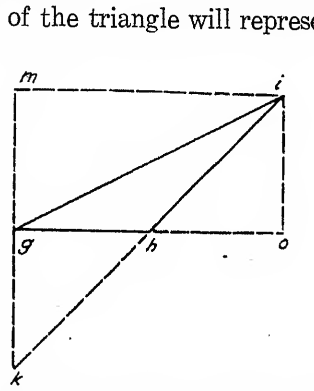

FIG. 4—PROJECTION OF FIG. 3 WITH ADDITIONAL CONSTRUCTION LINES

two forces on the messenger, $m\ k$ the total dead load acting vertically and $i\ k$ the resultant load on messenger acting in the direction of slope of messenger.

Therefore

$m\ k = W_c + W_m$, weight of contact plus weight of messenger, and since $m\ g = W_c$ = weight of contact (2)

then

$$g\ k = W_m = \text{weight of messenger} \quad (3)$$

and

$$g\ k/m\ g = W_m/W_c \quad (4)$$

The two triangles in the Fig. 4, $g\ h\ k$ and $h\ o\ i$, are similar since their corresponding angles are equal.

Therefore

$$g\ h/h\ o = g\ k/i\ o \quad (5)$$

But

$$i\ o = m\ g, \text{ by construction} \quad (6)$$

Therefore

$$g\ h/h\ o = g\ k/m\ g \text{ from 5 and 6} \quad (7)$$

Also

$$g\ h/h\ o = T_m/T_c \text{ see Appendix III} \quad (8)$$

Therefore

$$T_m/T_c = W_m/W_c \text{ (axiomatic from (4), (7), and (8))} \quad (9)$$

It has thus been demonstrated that the ideal inclined catenary construction with zero length of shortest hanger is a true construction and that the relation of weights and tensions of members is as given in the formula.

The usual inclined catenary, however, has a shortest hanger of some length. If the contact line of such usual catenary is ideals,[4] it also has parallel hangers and the formula will also show the relation of its weights and tensions.

4. See previous definition.

This can be demonstrated by considering Fig. 5. On Fig. 5, $g\ h\ i$ is the $g\ h\ i$ of Fig. 3; $g\ s\ p\ h$ is another figure showing the projection of the more usual inclined catenary with shortest hanger $h\ p$ of some length. The only difference between the ideal inclined catenary $g\ h\ i$ and the usual inclined catenary illustrated is in the length of hangers. The other factors in the two are identical, weight of contact, tension of contact, weight of messenger, and tension of messenger. Consequently, the usual inclined catenary with ideal contact line and parallel hangers will be in agreement with the formula. And conversely, if weights and tension are chosen in accordance with the formula, an ideal inclined catenary results if the contact line is made ideal.

In demonstrating the formula it has been assumed that the hangers were without weight. Practically, they will have some weight, this usually approximating five per cent of contact and messenger weight. This weight will have an effect on the actual slope and sag in practical construction and must be provided for. If the hanger weight is included by prorating it and including with contact and messenger weights, the ratio of weights and consequently of tensions in the formula is not changed so that if a basic contact tension is selected, the messenger tension will be fixed regardless of whether hanger weights are considered or not. Therefore, in preliminary determination or selection of messenger tension, hanger weights can be safely ignored.

In determining slopes of hangers and slopes of messenger and sag of messenger, however, the weights of hangers must be taken into consideration. Such consideration, however, will not destroy the value of the formula in practical applications as the distortion due to the hanger weights in the extreme case, *i. e.*, the case where the shortest hanger is assumed to have zero length, is practically negligible.

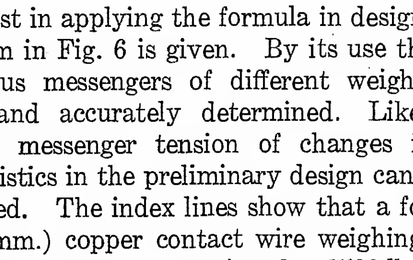

FIG. 5—PROJECTION OF FIG. 3 WITH PROJECTION OF INCLINED CATENARY WITH LENGTHENED HANGERS

To assist in applying the formula in design work the nomogram in Fig. 6 is given. By its use the tensions for various messengers of different weights can be quickly and accurately determined. Likewise, the effect on messenger tension of changes in contact characteristics in the preliminary design can be readily determined. The index lines show that a four naught (106-sq. mm.) copper contact wire weighing 0.641 lb. per ft. (0.956 kg. per m.) tensioned to 2500 lb. (1135 kg.)

requires that a messenger weighing 2.37 lb. per ft. (3.54 kg. per m.) have a tension of 9240 lb. (4200 kg.) in order to satisfy the design conditions for ideal inclined catenary.

On the assumption that tangent construction conditions are also satisfied by the indicated curve messenger tension—*i.e.*, that a practical span and sag results—the next step in the order of design is to find the length of hangers in the tangent span selected. Fig. 7 is a diagram method based on the formula and the supplementary truth that for every tangent hanger, a corresponding inclined hanger for each degree of curve can be selected.

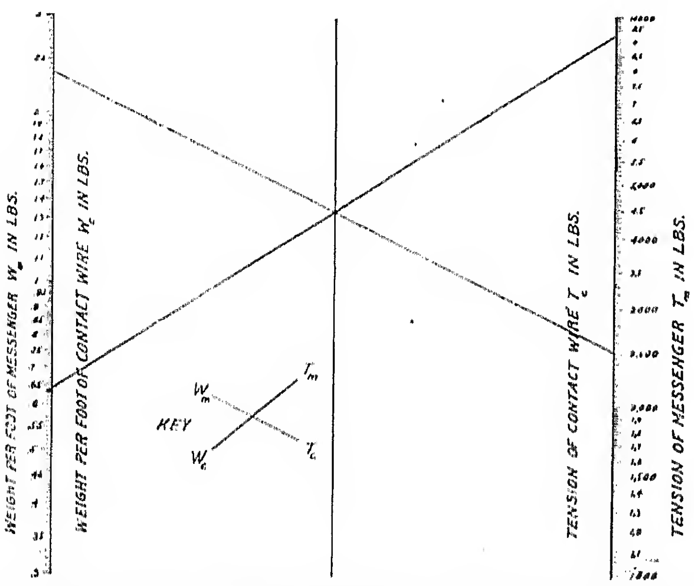

Fig. 6—Nomogram of Fundamental Formula for Design of Ideal Inclined Catenary $T_m/T_c = W_m/W_c$

The basic formula (**9**) is independent of span length or degree of curvature. Furthermore, the quantities in the formula are kept constant in all spans and curves in the usual practical alinement. Hence, any tangent span length may be selected as a basis for a group of curves of same span length. With the hangers of the basic tangent span selected, the corresponding hangers of any of the related curve spans can be found by simple mathematical operations. The operations are performed graphically in Fig. 7.

Fig. 7 is constructed by laying off the tangent half-span with the customary assumption that it is a parabola and that the contact line is horizontal. The tangent hangers of the half-span are drawn in to scale at desired hanger positions with the contact line shown the proper distance below the messenger. The slope lines of the inclined hangers for the various degrees of curvature are determined by laying off W_{ch}, the unit weight of contact with prorated hanger weight vertically and the radial load[5] per unit of contact horizontally and drawing in the straight lines through zero and such points. The radial load per foot of contact is T_c/R, where R is the radius in feet of the curve.[6] The length of the inclined hanger is found by projecting horizontally from the corresponding tangent hanger length to the proper slope line. The angle with the vertical is found with a protractor. A tabulation of corresponding hanger and angles is shown in Table I.

5. See Appendix IV.

TABLE I
LENGTH AND ANGLE OF HANGERS

		1 Deg.		2 Deg.	
Alinement hanger no.	Tangent length in inches	Angle Deg.	Length	Angle Deg.	Length
1	9½	33½	12	52	16
6	12½	"	15	"	21
3	18½	"	22½	"	30½
4	27½	"	33	"	45
5	40	"	48½	"	66
6	54½	"	65½	"	89½

Both length and angle values in Fig. 7 can be readily checked if desired by the use of appropriate formulas.

The formula for determining the length of tangent hangers is based on commonly known characteristics of the parabola:

$$h = e + (4\,x^2\,s / L^2) \tag{10}$$

where

h = hanger length,
e = length of shortest hanger at lowest point of sag,
x = horizontal distance of hanger from lowest point of sag,
s = sag of the half-span considered,
$L/2$ = length of the half-span considered.

Fig. 7 Diagram for Graphically Determining Hanger Lengths and Angles

The corresponding inclined hanger length is determined by multiplying the tangent hanger length by multiplier as found in the following formula:

$$(T_c^2/R^2 + W_{ch}^2)^{1/2} / W_{ch} \tag{11}$$

The angle of hanger with vertical is

$$\mathrm{Tan}^{-1}\, T_c / R\, W_{ch} \tag{12}$$

The practically standard method of designating

6. See "Notes on Catenary Construction" by Sidney Withington, *Franklin Institute Journal*, Dec., 1914, p. 720.

hangers is to give their angle of inclination from the vertical and their length from center line of messenger to center line of contact. Also, the practically standard term for designating the horizontal distance between center lines of contact and messenger is "the displacement."

The length of the shortest hanger is usually taken as 6 in. This length selection, however, depends on various conditions and the hanger may be made shorter or longer as circumstances may require. In Fig. 7 the shortest hanger is 9 in.

With the design following the formula, it can be demonstrated that the inclination of the suspension string is the same as that of the hangers in all cases, *i. e.*, with any length of shortest hanger.

The basic formula can be put into the form

$T_c/W_{ch} = (T_m + T_c)/(W_{mh} + W_{ch})$, a continued proportion (13)

Therefore

$T_c/W_{ch}\, R = (T_m + T_c)/(W_{mh} + W_{ch})\, R$, multiplying both sides of (13) by $1/R$ (14)

The formula for angle which the hanger makes with the vertical is previously given as

$$\tan^{-1} T_c/W_{ch}\, R \qquad (12)$$

The angle with vertical made by the suspension string is

$$\tan^{-1} (T_m + T_c)/(W_{mh} + W_{ch})\, R \qquad (15)$$

This is so since the suspension string takes a position in the direction of the resultant of the two forces acting on it, the vertical force due to dead load of span $(W_{mh} + W_{ch})\, L$ and the horizontal force $(T_m + T_c)\, L/R$. And hence the tangent of the vertical angle is

$$((T_m + T_c)\, L/R)/(W_{mh} + W_{ch})\, L \qquad (16)$$

which upon simplification becomes

$$(T_m + T_c)/(W_{mh} + W_{ch})\, R \qquad (17)$$

Therefore the two angles are equal since their tangents are equal. (From (12), (17), and (14).)

Consequently, the total displacement of the insulator support from center line of contact wire may be found by considering the suspension string as an extension of the theoretically longest hanger at the point of support; see Fig. 7. This is true only of the ideal inclined catenary.

With a theoretical "zero" length of shortest hanger, the displacement d of the messenger for a given contact and messenger and a given curve and span is a constant quantity and does not change with variation in the design contact tension and messenger tension.

Let

d = the displacement.

W_{ch} = unit weight of contact with hanger weight prorated

W_{mh} = unit weight of messenger with hanger weight prorated

Since W_{ch} and W_{mh} are assumed constant,

$$W_{ch}/W_{mh} \text{ is a constant} \qquad (18)$$

Since the design formula $W_{ch}/W_{mh} = T_c/T_m$ is assumed to be followed, then

$$T_c/T_m \text{ is also a constant} \qquad (19)$$

Likewise the various forms of the formula obtained by composition are constants.

$$(W_{mh} + W_{ch})/W_{ch} \qquad (20)$$

and

$$(T_m + T_c)/T_c \qquad (21)$$

are constants. With zero length of shortest hanger the length of longest hanger at support in tangent spans is the same as the vertical sag, *i. e.*,

$$S = (W_{ch} + W_{mh})\, L^2/8\, T_c \qquad (22)$$

The angle which the inclined hanger at support makes with the vertical will depend on the tension in the contact wire. The tangent of this angle is,

$8\, T_c\, d/(W_{ch} + W_{mh})\, L^2$ (displacement d over sag (22)) (23)

It is a variable.

Another expression for the value of tangent of hanger angle is

$$(T_m + T_c)/R\, (W_{ch} + W_{mh}) \qquad (24)$$

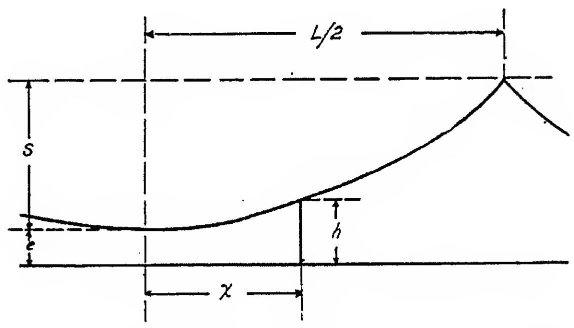

Fig. 8—Diagram for Tangent Hanger Length Formula

which gives the slope of the supporting insulator string.

As the two angles are equal, their tangents are equal.

$$8\, T_c\, d/(W_{ch} + W_{mh})\, L^2 = (T_m + T_c)/R\, (W_{ch} + W_{mh}) \qquad (25)$$

and

$$8\, T_c\, R\, d = (T_m + T_c)\, L^2, \text{ simplifying (25)} \qquad (26)$$

and

$$d = L^2/8\, R \times (T_m + T_c)/T_c \qquad (27)$$

$L^2/8\, R$ = middle ordinate of curve for span of length L and radius R and is a constant for a given curve and span[7] (28)

Since $(T_m + T_c)/T_c$ is also a constant as per preceding (21), then d is a constant as it is the product of two constants. If the shortest hanger is given some length, however, the displacement does not remain constant. Another disturbing factor in the total displacement is also introduced by the use of a suspension string of insulators for supporting the catenary.

Probably the most complicated part of the design of an inclined catenary is that covering the transition

7. See Allen, R. R., "Curves and Earthwork," 1903 edition, p. 42.

from the tangent to the body of the curve. This section of the overhead is somewhat similar to a spiraled section of the running track. With an inclined catenary designed according to formula, transition design is greatly simplified as the selection of hangers of suitably varying angle and length becomes a relatively simple process by means of the diagram of Fig. 7.

Usually a simple design is economical and results in lowest cost for the duty performed. It is not proposed to demonstrate with mathematical exactness that the formula design of inclined catenary results in lowest over-all construction costs. The following analysis would indicate, however, that this is practically true.

Assuming equally good design of supporting structures, the combination of minimum loads consistent with minimum dimensions of catenary structure, both vertical and horizontal, should result in minimum supporting structures. If a messenger tension greater than that demanded by formula is selected by the designer, there will of course be a greater side load on the structures than if the formula were followed, since the side load varies directly as total wire tension. The dimensions may be reduced vertically somewhat but probably will not be reduced horizontally because of the distortion of the contact wire from the position parallel to center line of track.

If a messenger tension less than that of formula is selected in order to diminish the side load, the vertical and horizontal dimensions of catenary and of supporting structure will be increased as the sag is increased and although there may be a smaller effective side load, overcoming the distortion of the contact and messenger will require additional pull-offs and other changes such as auxiliary back-bones or more frequent supports with the probable net result of increased cost.

One of the greatest economic advantages of designing according to the formula is the resultant easy erection of the wires. All parts fit together naturally and there are minimum secondary stresses. The construction can be handled like a truss with members designed and connected properly, as compared to a truss in which members are not of proper length and in which the loads are carried eccentrically by the members. Cables are of course much more flexible than truss members and hence can be more easily pulled into connection with other members but nevertheless secondary stresses and distortion result with inexact design and must be provided for in the original design or as later experience dictates. With the inclined designed as per formula, the parts fit and come together easily so that the time and labor of erection and later maintenance become a minimum.

Design based on the formula also makes variations of the simple inclined catenary relatively easy. Double catenary, either with double contact or messenger or both, and staggered catenary on curve and tangent are examples of such variations. Furthermore, as is often desirable, if a stretch of chord construction is required, it can be readily introduced without complications between sections of inclined catenary.

The formula would appear to handicap design in that it selects but one messenger tension value and thus fixes the dimensions of the catenary on tangent as well as on curve after the other three factors, contact weight, contact tension, and messenger weight, are settled upon. There should be no objection to the limitations imposed if a reasonable construction results. If the resulting construction is not considered reasonble, it is still possible to change the other factors of design such as contact material and tension as well as messenger material and resulting tension in order to better satisfy tangent conditions.

The result of following this method of design will be the eventual selection of several contact weight and tension conditions as standards so that for similar service on comparable lines there will be available a suitable standard. Such a condition should enable sound comparisons to be readily made of operating conditions on such lines.

Assuming that a contact wire of a given weight and tension relation is installed as tentative standard practise, the inclined catenary construction has an inherent tendency to maintain this relation of weight and tension constant for a given temperature over a period of years, as the operating slope of hangers and position of contact wire over track depend on such relation being kept constant. The tension of the contact wire is a much more important design factor in any inclined catenary than in chord construction. It is in fact the basic or starting factor. In the chord type of construction the tension of the contact wire may vary over a wide range and not produce any noticeable effect on the shape of the construction. Two lines or sections of chord construction may appear exactly alike and yet have very different contact tensions and hence different collecting characteristics. This is not so of inclined catenary constructions. If they are otherwise alike, their contact tensions are also alike and consequently their collecting characteristics will be alike and they will stay alike with similar temperatures. True operating comparisons can then be made of such overheads under the same or differing services with the gradual result of continually improving the standards. The economic result of such a condition should be very satisfactory. It would only be a matter of time before the most economically designed and operated line or lines for certain conditions would be found.

It is interesting and valuable to use the formula as a check on already existing and operating inclined catenaries. Investigation shows that practically all lines heretofore installed depart more or less from this criterion, some more than fifty per cent. This might indicate one of two conditions. Either the formula application is not practically necessary and inclined catenary is very adaptable or present inclined catenary construction designs are subject to refinement.

Data showing the departure from the formula on certain important lines already installed are as follows:

Canadian National Railways. From data which appeared in the *Railway Age*, May 2, 1925, in article, "New Catenary Construction on the Canadian National," and elsewhere, the following values were secured:

$$W_m = 0.745 \text{ lb.},$$
$$W_c = 0.641 \text{ lb.},$$
$$T_c = 2400 \text{ lb.},$$
$$T_m = 3600 \text{ lb.}$$

T_m as per formula should be 2790 lb. Hence, tension used is 30 per cent higher.

Pennsylvania Railroad. Philadelphia to Paoli Electrification. From data in *The Electric Journal*, February, 1916:

$$W_m = 0.510 \text{ lb.},$$
$$W_c = 0.509 + 0.320 = 0.829 \text{ lb.},$$
$$T_c = 3000 + 1000 = 4000 \text{ lb.},$$
$$T_m = 3500 \text{ lb.}$$

T_m, according to formula, should be 2470 lb. Hence, tension used is 42 per cent higher.

New York, Westchester, and Boston Railway. Data in Sidney Withington's article, *Journal of Franklin Institute*, Dec., 1914, are as follows:

$$W_m = 0.810 \text{ lb.},$$
$$W_c = 0.641 + 0.558 = 1.199 \text{ lb.},$$
$$T_m = 4900 \text{ lb.},$$
$$T_c = 3500 \text{ lb.}$$

T_m, according to formula, is 2370 lb. Hence, tension used is 107 per cent higher.

N. Y., N. H., & H. R. R. Danbury Branch. From page 313 of *Electric Railway Journal* for August 29, 1925:

$$W_m = 0.668 \text{ lb.},$$
$$W_c = 0.641 + 0.641 = 1.282 \text{ lb.},$$
$$T_c = 1600 + 1815 = 3415 \text{ lb.},$$
$$T_m = 3900 \text{ lb.}$$

T_m, according to formula, should be 1785 lb. Hence, tension used is 118 per cent higher.

Midi Railway of France. From data on page 175 of *Le Génie Civil*, August 25, 1923, the following information is obtained:

$$W_m = 0.65 \text{ kg.},$$
$$W_c = 0.89 + 0.89 = 1.78 \text{ kg.},$$
$$T_c = 700 \text{ kg.} + 700 \text{ kg.} = 1400 \text{ kg.},$$
$$T_m = 1350 \text{ kg.}$$

According to formula, T_m should be 510 kg. Hence, tension used is approximately 164 per cent higher.

A number of lines has been designed in accordance with the formula and several have been constructed and are in process of construction. Model spans have also been built. The results indicate that the formula is a very satisfactory and practical guide. The usual inclined catenary is a practical though somewhat empirical design. The design based on the discovered formula is proposed as an improvement as it is both practical and scientific.

The formula gives an exact statement of the relations of the various design factors involved. It is just as true as the equation of the parabola and to question a design based on it is comparable to questioning the use of the parabola formula in the design of the usual catenary.

The simplicity of the discovered formula indicates that the ideal inclined catenary construction with its two parabolas and connecting parallel hangers is a special shape which is closely allied to other geometrical shapes, the cone, the cylinder, and the sphere. And just as these are inherently best suited for certain mechanical purposes, the ideal inclined catenary shape

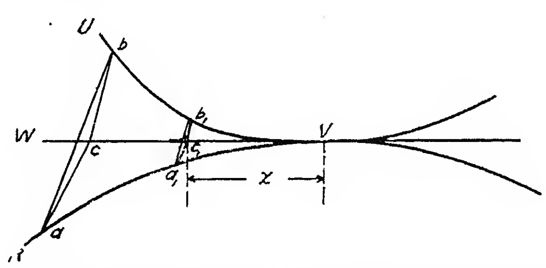

FIG. 9—SKETCH USED IN PROOF THAT TRACE OF ELEMENTARY HANGERS IS A PARABOLA

is especially adapted for railway overhead construction on curves. It fits the track alinement perfectly.

Appendix 1

Demonstration of proof that curve $U\,V$ is a parabola.

$R\,V$ = parabola of contact wire, by construction and definition,

$a\,b$, $a_1\,b_1$ = parallel elementary hangers supporting contact wire,

$W\,V$ = intersection of horizontal plane of contact wire with inclined plane of messenger slope,

$U\,V$ = curve formed by elementary hangers $a\,b$, $a_1\,b_1$, etc., piercing plane of messenger slope at points b, b_1, etc.

To prove curve $U\,V$ is a parabola:

Pass vertical planes through elementary hangers $a\,b$, and $a_1\,b_1$ parallel to principal axis of parabola.

Triangles $a\,b\,c$ and $a_1\,b_1\,c_1$ are formed by the intersections of such parallel planes with horizontal plane of contact wire and inclined plane of messenger slope.

Triangles $a\,b\,c$ and $a_1\,b_1\,c_1$ are similar since their corresponding sides are parallel **(29)**

$a\,b$ is parallel to $a_1\,b_1$, by construction **(30)**

$b\,c$ is parallel to $b_1\,c_1$, intersections of two parallel planes by a third plane **(31)**

$a\,c$ parallel to $a_1\,c_1$, same reason as **(31)** **(32)**

$$a\,c/a_1\,c_1 = b\,c/b_1\,c_1 \quad \textbf{(33)}$$

but

$$a\,c/a_1\,c_1 = x^2/x_1^2, \text{ ordinate of parabola } R\,V \quad \textbf{(34)}$$

Therefore,

$b\,c/b_1\,c_1 = x^2/x_1^2$, axiomatic (33) and (34) (35)

Therefore curve $U\,V$ is a parabola, since it has the properties of a parabola.

Therefore, the curve which the assumed elements trace in their intersection of the inclined plane of messenger slope is a parabola.

Likewise, the projection of the messenger on the horizontal plane of the contact wire is demonstrated to be a parabola.

Appendix II

Proof that $U\,V$ represents the true position of the inclined messenger.

Assume $a\,b$ is the position of longest hanger of some given span and that b is the point of attachment of hanger to messenger. The messenger with the calculated resultant load can be so tensioned as to pass through b and V and it will take the shape of a parabola.

Only one parabola can be constructed with vertex at V and passing through b. Hence, the messenger will take the shape of the parabola $U\,V$. Hence, the elementary hangers will intersect the plane in the parabola $U\,V$ formed by messenger and therefore the assumed construction is demonstrated to be a true construction.

Appendix III

Proof that tensions of contact and messenger vary inversely as their horizontal sags.

In Fig. 10,

$a\,b$ = length representing the sag of the inclined messenger in feet (36)

$a\,c$ = length representing the horizontal sag of projection of messenger on horizontal plane in feet (37)

$e\,a$ = length representing resultant load on messenger in pounds (38)

$d\,e$ = length representing dead load on messenger in pounds (39)

$d\,a$ = length representing horizontal load on messenger and also on contact wire in pounds (40)

$f\,a$ = length representing middle ordinate or horizontal sag of the contact parabola in feet (41)

$T_m = (e\,a)\,L^2/8\,(a\,b)$ parabola formula (42)

$T_c = (d\,a)\,L^2/8\,(f\,a)$ parabola formula (43)

$T_m/T_c = (e\,a)\,(f\,a)/(a\,b)\,(d\,a)$, dividing (42) by (43) (44)

$(d\,a)/(e\,a) = (a\,c)/(a\,b)$, similar triangles (45)

and

$(d\,a)/(a\,c) = (e\,a)/(a\,b)$, from (45) (46)

Therefore

$T_m/T_c = (d\,a)/(a\,c) \times (f\,a)/(d\,a)$, substituting in (44) (47)

Therefore

$T_m/T_c = (f\,a)/(a\,c)$, simplifying (47) (48)

Therefore the tensions are in inverse proportion to the horizontal sags.

Appendix IV

Proof that the radial load caused by a contact wire of a given tension and circular curve is practically the equivalent of the uniform horizontal load of a parabola with same tension at the middle of span and with sag equal to middle ordinate of arc of circular curve.

$T\,R = P$ = unit radial curve load[8] (49)

$m\,o$ = middle ordinate[9] $= L^2/8\,R$ (28)

The sag $S = m\,o$ by assumption (50)

$T = w\,L^2/8\,m\,o$ = parabolic catenary formula (51)

where w = unit load on horizontal parabolic catenary.

Prove $P = w$ (52)

$R = L^2/8\,m\,o$, from (28) (53)

$8\,T\,m\,o/L^2 = P$, substituting (53) in (49) (54)

and

$8\,T\,m\,o/L^2 = w$, from (51) (55)

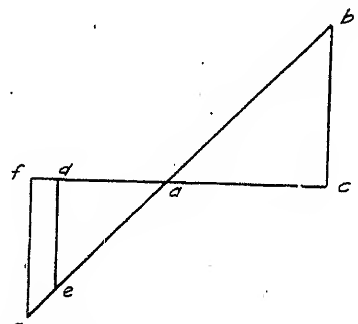

Fig. 10—Sketch Showing Projection of Ideal Inclined Catenary With Forces Acting On It

Therefore

$P = w$ axiomatic, from (54) and (55) (56)

TABLE OF LETTERS OR SYMBOLS

W_c = weight of contact wire in pounds per linear foot,
T_c = tension of contact wire in pounds,
W_m = weight of messenger wire in pounds per linear foot,
T_m = tension of messenger wire in pounds,
a = contact wire in Fig. 1,
b = messenger wire in Fig. 1,
c = inclined hangers in Fig. 1,
d = displacement of messenger,
f = projection of messenger on horizontal plane, Fig. 2,
W_{ch} = unit weight of contact wire with prorated hanger weight in pounds per linear foot,
R = radius of curvature in feet,
h = hanger length,
e = length of shortest hanger at lowest point of sag,
x = horizontal distance of hanger from lowest point of sag,

8. Withington, *Franklin Institute Journal*, Dec., 1914, p. 720.
9. Close approximate formula, Allen, "Railroad Curves and Earthwork," 1903 edition, p. 42.

s = sag of half-span considered,
L = length of span,
W_{mh} = unit weight of messenger wire with prorated hanger weight in pounds per linear foot.

Discussion

PAPERS ON OVERHEAD CONTACT SYSTEMS

(VIELE, BROWN, THORP, WADE AND LINEBAUGH, AND JORSTAD)
DETROIT, MICH., JUNE 24, 1927

H. F. Brown: Mr. Viele's paper emphasizes many points which are in line with similar experience on the New Haven system such as

1. The advantage of the auxiliary wire above the working conductor.
2. The necessity for proper steadying devices for the trolley, on both tangent and curve construction, especially against transverse wind loads.
3. The avoidance of long spans in exposed locations.
4. The advantage of locating sectionalizing and splicing devices at or near the supports.
5. The avoidance of hanger members which do not make a positive contact with both the messenger and the contact.
6. The importance of correlating the pantograph design with that of the overhead contact system, and the possibility and desirability of further refinement in the pantograph design.

In connection with the tests described, it would be of interest to know what effect the tensions of the auxiliary and the contact have on the amplitude of movement at the support point. Lower tensions, especially of the auxiliary, might offer an improvement. It would also be of interest to know the effect of the contact-wire tension on the speed at which the oscillations travel along the wire; also a comparison of the effect of the very light rods now being used on the newer installations, as compared with the columnar effects of the older, heavier types.

M. W. Manz: The amount of rise of the pantograph wire in any catenary span would be in proportion to the unloading or in proportion to the pantograph pressure. That can be laid out rather accurately with the force polygon, and if one follows the movement of the pantograph through a number of locations one gets an unloading diagram similar to the curve Mr. Viele has presented.

There is a rather peculiar thing about that type of diagram; the movement of the system is the largest at the center of the span. Has any thought been given to the possibility of increasing the weight of the system at the center of the span as opposed to increasing it near the supports which now happens due to the longer hangers? In other words, if you take the diagram and unload it at various points, you will find that an unloading at the support has much less effect on the system than at the center of the span. Has any consideration been given to the possibility of some correction, perhaps, for the unloading at the center as opposed to more unloading at the supports?

In connection with the long wave motion, which you have with a number of pantographs in a span, with a number of spans there is a rather interesting combination. Has any observation been made as to the extent of movement of the suspension insulator? When you unload a span, you reduce the tension. When you do that, the insulator will swing, giving an effect of balancing the tension back through the system. There might be another interesting point to consider for future investigations; can the loadings of the messenger be decreased as you approach the supports in such a way that the lift of the system is uniform?

G. I. Wright: We on the Illinois Central are considering the application of roller bearings to our pantographs—something that has not been done generally in this country, but I believe has been done abroad.

In both Mr. Viele's and Mr. Brown's papers, they mentioned a provision that they thought necessary to make for flashover of insulators—burning the construction and so on. I might say that due to the system we use and the design of it, we have had no flashover of insulators and practically no burning of wires. The only burning of wires we have had, except that caused by a direct stroke of lightning, has been the burning of the contact wire where the pantograph ran from a live section to a dead section on which there were a large number of trains standing. In leaving the gap, this caused an arc which was maintained, and burned the wires.

I might state that in order to prevent this burning we are installing dead-section signals which will stop a train from passing from a live to a dead section.

The fine results due to the elimination of burning and arcing are also largely due to the high-speed breaker protection we have on all feeders energizing the catenary.

In Mr. Jorstad's article, I thought possibly he gave a wrong picture of the popularity of the inclined catenary. I believe that both types have their use and their field, and that certainly the chord construction is better for a great many installations, particularly where there are few curves and considerable copper is required.

Mr. Jorstad listed eleven railroads which use inclined catenary, and stated that this indicated that this would be a future standard overhead. There are very many important railroads which use the chord construction.

Mr. Jorstad also said that in using inclined catenary only two wires were necessary whereas with chord construction three or four are used. I believe that is limited to short-span lifting-hanger construction, while two wires would not be feasible for long-span construction generally used for heavy electrifications.

Apparently, Mr. Jorstad's method of design greatly simplifies something that in the past has generally been considered very complicated, and such a simplification should be welcomed by all.

Norman Litchfield: As consulting engineers for a number of railroads, we have been closely connected with the development of the modern catenary, and a short review may therefore be of interest.

The first major installation of high-voltage catenary was on the N. Y., N. H. & H. R. R., in 1906, between Woodlawn, N. Y. and Stamford, Conn., the main line construction using two messengers with diagonal hangers forming a *B* with the trolley.

On the electrification of the Elkhorn grade of the N. & W. R. R., in 1912 we employed a single catenary for both main line and yards, the necessary stability of the trolley wire being obtained by a cross-span wire installed only at points exposed to winds. The catenary was supported by suspension insulators hung below the body strand, thus eliminating insulation in the latter between tracks. The same construction was used by us on the Paoli electrification of the P. R. R. and has since become practically a standard.

The original New Haven construction used a square, latticed column, bolted to a concrete foundation. To provide a lighter appearing structure, and to reduce first cost and maintenance, the N. & W. R. R. and the P. R. R. adopted tubular poles set in cored holes in concrete foundations, the poles being guyed to concrete anchors at points of curve pull.

On a further extension of the N. & W. R. R., rolled-steel H-columns were used for the first time, with structural bases bolted to the foundations.

For the Virginian Railway electrification in 1923, we used H-columns with a pre-cast concrete base, cast on the pole at a central manufacturing yard. These were set in holes sheathed with a section of corrugated steel culvert pipe, then wedged in place, and backfilled.

During the past year we have been engaged in the electrification of the Bay Ridge freight line owned by the New York Connecting and the Long Island Railroads, and have used plain H-columns set in culvert pipe, then wedged in place and the pipe filled with concrete.

To obtain a very light appearance and a clear view of signals, on the Paoli electrification, a cross catenary was used for the support of the messenger and trolley, this being its first general application to main-line work, although it had been used previously in the East Port Chester yard of the N. Y., N. H., & H. R. R.

Prior to the Virginian electrification, we had utilized galvanized steel wire and galvanized castings for the support of the messenger and trolley wire. On the Virginian, non-corrosive materials were used for the messenger and the trolley hangers (the two live elements above the trolley). For the Bay Ridge electrification, a further advance was made by the employment of non-corrosive hangers and wires throughout, including the cross-catenary.

Electrification is now under way of the P. R. R. Company's suburban service between Philadelphia and Wilmington which uses all non-corrosive materials. It is on a portion of this line that the interesting type of steady which is described in Mr. Viele's paper will be used.

At the time we undertook the Elkhorn grade electrification, we found the mathematics of the catenary system in an undeveloped state, the practise being to calculate the hangers only for those spans which followed around a uniform track curve, it being left to the construction forces to cut and fit the irregular spans at transitions, etc. On this line it became imperative to find some method of calculating the irregular spans also, and an original theorem was therefore developed by our engineers. This has since become generally used, and is described in Mr. Brown's paper. It should be remembered that while discussion of the mathematics is of value, nevertheless catenary design is largely empirical, requiring judgment and experience to produce an economical and smooth-running line.

H. S. Richmond: In abolishing the trolley pull-offs on high-grade and high-speed systems, by experience it was found necessary to meet the condition which demands that the trolley curve of one span shall be tangent to that of the adjacent span opposite the point of support. The trolley curve is not a true circle, but if the above condition is met, it forms a continuous and graceful curve, lying in a horizontal plane at the temperature for which the computations were made. We have deduced formulas by which spans are thus matched together or "balanced" both on regular curvature and on transitions.

The formula by which spans are "balanced" on a regular curve is

$$U = \frac{100008725\left(1 - \dfrac{T}{M}\right)\phi}{d\,\phi/d\,x}\,D\,S$$

and the maximum deviation Δ of the form of the trolley curve from the true circle is given by the formula:

$$\Delta = S\,D\left[\frac{S}{45900} - \frac{\phi - 1}{11470\,d\,\phi/d\,x}\right]$$

Here

S = the span in feet.
T = the combined trolley and auxiliary tension.
M = the messenger tension.
D = the track curvature in degrees.
U = the horizontal offset between messenger and trolley.
ϕ = the ordinate of the fundamental trolley curve referred to the system axis.

and

$d\,\phi/d\,x$ is the derivative of ϕ with respect to axial dimension, the particular values of the curve and its derivative at the point of support being used.

The deviation Δ, we have found to be a very small quantity and not of significance as regards conformity of trolley to pantograph center. In this we take exception to Mr. Brown's citation of this point as being an important limitation in the use of the inclined system. On the contrary, we find that the real limitations of this system for moderate curvatures lies in the length of the horizontal offset between contact wire and messenger at points of support and the temperature variation in vertical and lateral position of the contact wire.

J. C. Damon: Mr. Jorstad noted that in systems investigated, the tension used for the primary messenger of the catenary construction was considerably higher than his formula would give.

In the recent past, the tendency for catenary construction seems to have been to use very high-strength material for the messenger and to keep the sag as low as possible. Under these conditions, the stretch of the cable furnishes a large proportion of the excess length of the catenary curve over the straight-line distance between supports, and with a given uplift from the pantograph, the tendency for the catenary system to rise is consequently very great.

When the tension in the messenger per-pound-weight of the catenary system is reduced, the sag must be increased; but, in turn, there is less tendency for the catenary system to rise because of the pantograph uplift.

With the lower tension in the messenger cable, there is a greater variation of the height of contact wire due to temperature variation, but less variation due to the uplift of the pantograph.

Recently, there has been a tendency to put feeder capacity into the messenger, which generally increases the weight of the messenger and, in consequence, due to the pantograph, reduces the upward movement of the contact wire. By using a moderate tension and putting the necessary feeder capacity into the messenger, some systems get no appreciable wave traveling ahead of the pantograph. The Chicago, North Shore, & Milwaukee Railroad, which uses the heavy type of construction with feeder capacity in the messenger, is, of course, a low-voltage railroad and quite different from the Pennsylvania main line; but it has an entirely non-rust construction of very heavy messenger, which has given satisfaction at fairly high speeds. The Illinois Central Railroad is another system in which the feeder capacity has been put in the messenger and has operated in a very satisfactory manner.

Mr. Viele contradicted the statement in my verbal discussion and stated that the heavier messengers with lower-tension per pound did not reduce the wave which went ahead of the pantograph. We are not, however, as far apart as our necessarily brief statements in the very limited discussion permitted would make it appear.

If there were absolutely unrestricted longitudinal motion of the messenger, Mr. Viele's statement would be correct and my statement would be wrong. On the other hand, if no longitudinal motion of the messenger from one span to another were possible, Mr. Viele's statement would be wholly wrong and mine, correct.

In actual practise, Mr. Viele has developed an extremely flexible catenary support system which approaches somewhat, although not entirely, the conditions of his assumption. On the other hand, most of the existing catenary systems, and, I venture to predict, a great many of the future catenary systems, will have bridges with saddle insulators, or short strings of suspension insulators, and conditions will be more nearly those of a completely restricted than of an entirely unrestricted longitudinal motion—in which case my statements, which were relative only, will be correct.

A. G. Oehler: My question is essentially an elaboration of what has already been introduced by Mr. Manz. I should like to know how much the loop hanger does offset the increased rigidity at the points of support? How much is this variation in rigidity corrected by the use of a heavy contact wire, and is it or is it not desirable to use a flexible hanger to minimize this difficulty? Finally, is it necessary to worry about it?

K. T. Healy: It seems unfortunate that no place has been

given in these papers to study the overhead distribution system costs. The future extension of electrification depends largely upon the abilities of the engineers and manufacturers to reduce the initial costs of the improvement, other things remaining equal. And a considerable part of this reduction must come in the distribution system, as this makes up from 25 to 35 per cent of the total cost of the electrification. Therefore, it is essential that the design of the overhead distribution system should, as a means of lowering costs, look not only to satisfactory operation but also to economical utilization of material and labor of construction.

As a general rule, economies of design are effected by a close study of the conditions and requirements at hand and an ample allowance for them, at the same time confining the design to these only. The main conditions affecting overhead design are: first, amount of conductivity to be provided; second, speed and method of collection of the current; and third, climatic conditions.

The requirements of conductivity immediately make a line of demarcation between high- and low-voltage systems, systems in level country and in mountainous country, and multiple-track and single-track systems. With the high-voltage systems, under all but mountainous conditions, ample conductivity can be secured in two conductors, so that there is no reason, so far as conductivity is concerned, for going into design with more conductors. With the low-voltage systems, more conductors are necessary with the consequent heavier loadings on supporting structures and greater amounts of steel necessary in the structures.

The second condition affecting overhead design—namely, speed of collection,—imposes on main-line, high-speed tracks, requirements decidedly different from those on yard and siding tracks. To a large degree collection is a function of the ability of the collector to keep in physical contact with the overhead in spite of variation in height of the overhead or varying hardness of the overhead. The ability to follow variations in height is dependent upon the velocity and lineal rate of variation in the height of the overhead with a given effective inertia of the collector. In yard operation the speeds are low and the currents low, so that greater lineal rates of variation in height are allowable and consistent with good collection and the overhead distribution does not necessarily have to be of the full catenary type. In Europe, notable strides have been made in decreasing the cost of yard electrification by taking advantage of this fact. The Swiss have their Renens yard arranged with a modified direct suspension, with 116-ft. and 165-ft. spans. This has given very satisfactory operating results.

The Paris and Orleans Railroad, on its 1500-volt electrification, has followed the same trend and has wired its yards in the Paris area with a direct suspended system with cross-span supports. Thus, many economies are possible by designing yard distribution systems, not for mainline track requirements, but for yard requirements of low-speed and less exacting requirements of uniformity in contact wire.

The second condition also has to do with the method of collection. Here again it may be well to emphasize Mr. Viele's remarks to the effect that coordinated effort in the design of both pantograph and overhead is necessary for satisfactory operation and that this coordination may be carried even further to affect economies in cost. Certainly one of the most important factors in the ability of a collector to work well is the inertia of its moving parts. Here, European pantograph design has taken a different course from ours on high-voltage systems by introducing a secondary bow for the shoe, swinging about its own central axis and held in position by small springs. This has reduced the effective inertia of the collector many times, because this small bow, weighing only a few pounds, is all that has to move to follow the small irregularities of the trolley height. It then requires much lower pressures to keep continuous contact on the trolley wire with consequent reduced wear on both wire and shoe. At the same time, the pantograph itself is made much lighter, using wire guys instead of pipe for side bracing and snugger joints with less friction at the points of support and other axes. This requires less pressure to operate and makes a smaller area for wind and ice loads to affect. The effects of hard spots in the contact system are of course greatly diminished because of the much lighter weight behind the impact of the shoe on the hard spot. Experience shows that a single shoe will collect 180 amperes perfectly at 55 mi. per hr. and 250 amperes at 27 mi. per hour, and that the shoes will run from 5600 mi. in Switzerland to 15,000 mi. in Germany. The usual practise is to run with two pantographs up, which nearly doubles the life of the shoes. The greasing of the shoes seems to be a mooted question; the Swiss, for instance, are in favor of it and the Germans are not.

Mention has been made of the need of coordinated effort in pantograph and catenary design, but the importance of this in relation to reducing both initial and operating costs cannot be stressed enough. With the low currents of normal high-voltage overhead distribution and the resulting possibilities of reducing shoe pressure, the possible simplification in catenary design is considerable.

In all the high-voltage European electrifications, this coordination has resulted in a great saving. Pantograph pressures have been kept down to 79 lb., using aluminum shoes with negligible wear on contact wires. As a consequence they have been able to use a much lighter and simpler catenary system with only a messenger and contact wire. In the past, to cut out the hard spots of the hangers, they have operated with an auxiliary or intermediate wire, but with the flexible hangers they use, they have found this wire unnecessary. In some cases the flexible hangers are made of strand so as to make a low-resistance, non-heating connection between messenger and contact. Particular care has been taken to avoid hard spots; splicing is rare, the contact wire being in lengths sufficient to reach from anchor point to anchor point; push-offs and other devices with compression members are not used; rigid deflectors are not used; and pull-offs are made very light.

The Swedish State Railroad catenary may be taken as an example of this type of catenary designed for weather conditions comparable to ours and with a conductivity of about 260,000 cir. mils. The costs of the materials at our prices would be about $528 per mile for 80 sq. mm. copper contact, and $316 per mile for 50 sq. mm. copper messenger, a total of $844.

A corresponding example of American practise may be a 4/0 phono contact, costing $792, a 4/0 copper wire, costing $686, auxiliary clips, costing $35, and a 9/16-in. steel messenger, costing $316, or a total of $1829 per mile, nearly $1000 more per mile than the other for a slightly greater conductivity of 310,000 cir. mils. The unit weights of the two systems are 0.81 lb. per ft., for the first and 1.95 lb. with the American, requiring a pole designed for roughly twice the catenary loading. This, of course, means an opportunity for the saving of considerable weight in the steel structures. The Swedish construction, using two 5-in. channels for a self-supporting single-track line, is comparable to the 10-in. H-section poles in use in this country for similar construction.

H. F. Brown: Mr. Thorp's paper among other things brings out the importance of the catenary profile in determining the structure heights and catenary details, especially where the hanger rods depart from standard conditions. This is a very valuable check on the calculations.

The unit weights and required conductivity of the overhead system described are impressive, but, of course, are required for the low voltage used. This is further reflected in the size of the supporting structures. I believe 14-in. H-beams were used for the typical two-track bracket poles illustrated in Fig. 15 of the paper. For the lighter type of catenary permitted by the higher voltage used on the New Haven, a 12-in. section is ample for similar two-track spans.

While Wade and Linebaugh show the feasibility of designing an overhead contact system which can transmit and deliver very large currents, and also the possibility of collecting large amounts by sliding collectors moving at high speeds, one cannot escape questioning the economics of a system which requires more than seven pounds of copper per foot of track, in the contact system alone.

If electrification is to be economically applied to steam railroads on any large scale, it must be done on a basis which gives the minimum new capital requirements. One of the largest items is the cost of the distribution system. The trend should, therefore, be towards lighter designs rather than heavier, indicative of higher voltages.

It is noted that the test track described contains no turnouts, heavy curves, or low highway bridges. With the high pantograph pressures required, the real test of current collection will come at points of special construction, such as deflectors, pull-offs on heavy curves, and the hard spots under low bridges; and while such difficulties might be overcome, they nevertheless increase at least in proportion to the catenary weight, and the amount of current to be collected. The wear on both the collector shoe and the contact wire must be greatly increased under such conditions, even with lubrication.

Mention was made of the use of a 6/0 conductor as being undesirable. Our experience seems to indicate that there is a real field of use for such a wire on busy yard leads and ladder tracks, where traffic is dense, and pantograph passages very frequent, and we have installed 6/0 wire in such locations to secure longer wear.

One word about lubrication. This is something to be desired but difficult to secure in actual practise, especially on a large system. If the lubricant is applied to the pantograph shoe at the start of a run, it is soon worn off in the first few miles, and the terminal-track trolleys are the chief beneficiaries. Tests made on the New Haven seem to indicate that the best shoe mileage and least wire wear is secured with a mild-steel shoe, and a pantograph pressure of about 18 lb.

Pantograph design is capable of being greatly refined. Lighter weights, lighter pressures, and lower inertias, especially of the collector shoe itself, seem to be the chief desiderate, all of which are inconsistent with heavy current collection.

Mr. Jorstad, in his paper, limits the shape of the trolley alinement to that of a true parabola, and shows that his formula, which gives the ratio of the weights of the two opposing systems (messenger and contact) equal to the ratio of their respective tensions, applies to the parabolic shape.

The use of this formula would therefore limit the designer in the choice of sag, or would fix the weights and sizes of the main members (messenger and contact) regardless of their economic choice.

As an illustration, assume that a 4/0 copper wire is the required contact member, with a normal tension of 2000 lb. The unit weight is 0.641 lb. and from the formula,

$$0.641\ T_m = 2000\ W_m \text{ and } T_m = 3120\ W_m$$

If we assume a 7/16-in. steel messenger, which past experience has shown to be of ample strength, properly sagged, for a 4/0 wire, its unit weight is 0.415 lb. and the tension, by the above formula will be 1300 lb.

The resulting catenary will weight approximately, including hangers, 1.15 lb. per ft., which would give a sag in a 300-ft. span of nearly 10 ft. This is obviously too great.

To decrease this sag to an economic value, the tension must be increased, which, according to the formula, must be accompanied by an increase in weight. To produce a 5-ft. sag, it would be necessary to go to a messenger having a unit weight of nearly three times the above, since the total weight is rapidly increasing. Assuming a unit messenger weight of 1.6 lb., the equivalent messenger tension would then be 5000 lb., and the resulting total weight of the catenary would be 2.3 lb. with a sag of 5.17 ft. This messenger would be approximately $^7/_8$ in. in diameter, which is obviously not economically applied, as the material is not required for the low tension used.

It is true that the trolley tension may be increased. The ultimate strength of the wire assumed is approximately 8000 lb. but it should not be stressed much more than $^2/_3$ of this amount on account of the low yield point of copper, and the danger of permanent stretch. This limits the maximum working tension to about 5300 lb., and sets the normal working tension at about 3000 lb.

Then, from the formula,

$$0.641\ T_m = 3000\ W_m \text{ or } T_m = 4700\ W_m$$

For a 5-ft. sag, the messenger must weigh approximately 0.671 lb. per ft. and the tension would then be 3140 lb.

This indicates a 9/16-in. messenger, which, although more nearly the economic size, is nevertheless larger than required, and is not working to its full capacity. Further, the horizontal loads on the structures on curves, due to the trolley tension, have now been increased 50 per cent, requiring this additional strength in such structures.

If, however, the characteristics of the design will permit the application of Mr. Jorstad's formula, it presents a very valuable method, and greatly simplifies the calculation, since the shape is parabolic. It may be mentioned here that the earlier installations on the New Haven, where the spans were short, were designed on the theory that the shape was parabolic.

Sidney Withington: (by letter) The design of pantographs in this country just at present, is, I believe, the least developed part of any of the electric equipment. We depend upon a collecting device capable of variation in height up to 10 ft., as mentioned by Mr. Viele. The inertia of such apparatus is very great and at high speeds, as pointed out by Mr. Viele, this is a serious problem and requires a very considerable pressure against the wire to avoid arcing. This, in turn, limits the design of the catenary system. The standard pantograph used abroad, which employes a trailing bow above the main pantograph, would seem to be considerably more logical. The trailing bow, being relatively light, follows the wire satisfactorily even at relatively low pressures, and the result is a far lighter catenary design with consequent economies both of construction and maintenance and without serious limitation in the amount of current which can successfully be collected. The advantages which would accrue from an improved design of pantograph in this country would repay, I believe, a very considerable amount of study.

Mr. Viele mentions spans of 325 ft. for the catenary system. It has been the experience on the New Haven that unless the location is pretty well protected from wind, some form of lateral support for long spans is necessary between bents in order to prevent trouble due to wind under maximum conditions. These supports may be obtained in the form of bridles or additional independent steady spans, or by shortening the main span.

The form of support suggested by Mr. Viele is of interest. A somewhat similar arrangement was installed on the New Haven in 1919. Other things being equal, it is of advantage to separate mechanically, as far as possible, each track from the others, in order that trouble which may occur may be localized. One advantage of the scheme mentioned by Mr. Viele is that the insulators are not directly over the track, and where steam locomotives are operated along with electric operation this is of considerable advantage.

Mr. Viele mentions hard spots and their damping affect on the oscillation which proceeds ahead of the pantograph. On the New Haven electrification, where wood section breaks were used at points of high speed an approach was designed consisting of a sheet-steel member of light gage about 6 ft. long, with the idea of damping the oscillations before they reached the relatively heavy section break. It was, however, found that this was not necessary, and its use has been discontinued. It is of course true that so far as possible, wood-stick section breaks are not used at

points of high speed. Indeed, even splicing sleeves are eliminated so far as possible.

It may be of interest to note that on the New Haven electrification extensions installed in 1912 and 1913, the steel catenary supporting structures were designed to be self-supporting as units; that is, the corner connections between the truss and the posts were arranged to take the stress normal to the track due to wind, curve pull, etc., the anchor bolts at the base of the posts taking shear only. This is indicated in the shape of the posts, which taper down from the truss or corner connections.

This saved a considerable amount of concrete as compared with the original design wherein the posts were self-supporting and the concrete bases were obliged to take the entire overturning moment. There was some additional weight of steel and additional field labor, but the design resulted in considerable net saving.

In some of the supporting structures, especially those for six tracks, it was found advantageous to assume a point of contraflexure about 7 ft. above the top of the foundation. This resulted in some saving of weight of steel without much increase in the size of the foundation.

The magnitude of current collected from a trolley at 500, 1500, or 3000 volts is of course far greater, other things being equal, than that collected at 11,000 or 22,000 volts, and the problems are therefore of somewhat different nature when the lower voltages are considered, both from the point of view of current-carrying capacity in the catenary system itself, and what might be called the "commutation" at the point of contact.

The problem of sparkless collection of current is a function of the smoothness of the contact system, which in turn depends upon its uniformity of suspension—that is, the contact wire should be either free to move in a vertical plane easily at all points upon the passage of the pantograph collecting shoe, or should be relatively rigid at all points. Any change from soft to hard construction means sparking or arcing at high speeds. The real test of sparkless collection occurs at turnouts and at low bridges and other points where construction is limited by local conditions.

Mention is made of the freedom from burned messengers on the Chicago, Milwaukee, & St. Paul at loop hangers, which are employed on that system. The real test of efficiency of loop hangers would occur, I believe, only where the individual substation capacity feeding the system is relatively larger than is the case on the Milwaukee.

The design of pantograph shoe support with 4 in. of play between upper and lower position on the top of the pantograph is of much interest. It would seem that somewhat delicate adjustment would be necessary in order to maintain the supporting apparatus at the mid-position of its travel under normal conditions that it might be free to move up or down as roughness in the contact system required. Details of design to accomplish this would be of interest. Some data also would be of interest as to the mileage made by the "pans." The pressure of 40 lb. seems high when compared with that where less current-carrying capacity is required. A pressure of 40 lb. also means a necessarily heavy contact system, regardless of current-capacity requirements.

The economic limitations of any contact system, I believe, occur in the weight and expense of installation of the conductors and supporting structures rather than in the amount of current which can be successfully collected under conditions of high speed, and this should be considered in the design of an electrification installation. It is possible that the use of higher voltages, either alternating or direct current, would be justified in some instances by the saving of material in the contact structure.

S. M. Viele: Mr. Brown asked the effect of tension in the contact wire on vertical movement. We have not made any experiments on the basis of varying contact-wire tension. My opinion is it would not make any material difference.

Mr. Manz asked about the effects of unloading the span. Mr. Damon's remarks were along the same line. I do not nterpret upward deflections in the span on the basis of the possible impression that some have of that statement. If we assume a condition in which the span involved has a unit weight of 3 lb. per ft. and say a 300-ft. span, it means that the messenger is carrying roughly 900 lb. If we operate five pantographs on the span, it means that instead of carrying 900 lb., it carries 800 lb. This means that the sag in the span has to be reduced on account of the tension remaining practically constant. Therefore, the messenger sag will be decreased; the extra length of messenger will run back in the successive spans.

Now, if you change the contact tension, or if you change the loading of the span without change of pantograph pressures, it will not make a great deal of difference in the upward deflections with passage of the pantographs.

Mr. Oehler asked the question "What does it amount to?" Deterioration of contact wire has a very material bearing on how much it costs to operate such construction. Spliced contact wire means a deterioration of roughly five times that without splices. Whether we get a life of ten years out of it or 50 years is very material.

The question may also be asked "What are the relative effects of variation in height of contact wire?" Such effects are relatively small as compared with spliced effects. However, all variations of whatever nature which take place in the contact-wire height involve variations of pressure, both in enlarged and decreased pressures. Increased pressures mean increased wear; decreased pressures mean burning of the contact wire. Both result in increased maintenance cost. It is simply a question of the relative reduction of section which is produced by such variations in height, with the resulting cost. They have not been evaluated in money, though they have been evaluated in my mind as being worthy of study and the correction of value.

H. F. Brown: In answer to Mr. Litchfield I will simply state that the method of eliminating the cusp shown in Fig. 41 is admittedly an overcorrection. The importance of this correction is greater if the trolley tensions are lower. On the New Haven system, the tensions of the trolley and the auxiliary are lower, I think, than on many of the other systems mentioned here today. For that reason, the cusp effect is more important in their inclined design than it is where the trolley tensions are higher, and the method used in the paper is shown instead of the one referred to by Mr. Richmond because it was desirable to make this correction apply to all conditions involving even high temperatures as well as the normal temperatures. It is true that if one goes into the mathematics of the paper, the method suggested by Mr. Richmond is absolutely correct for normal conditions.

R. E. Wade and J. J. Linebaugh: Mr. Brown, in his written discussion with reference to tests on the collection of large currents from overhead wires as conducted at Erie, Pa. mentions the use of "more than 7 lb. of copper per ft. of track in the contact system alone."

The actual total weight of copper, installed per ft. of track for the tests involving the unusually large current values quoted, and for both feeder and contact, was 4.7 lb. maximum with 1,000,000 cir. mil feeder messenger and 3.92 lb. in the section with 750,000 cir. mil feeder messenger. With multitrack work and automatic cross ties, these weights would be reduced even for the lower voltages used.

While it is true that the recorded tests were conducted without deflectors, hard spots under bridges and pulloffs on heavy curves, temporary low bridges were later installed, and satisfactory collection demonstrated with a 1 per cent gradient in contact wires. Experience on lines in operation shows that with two contact wires, flexibly supported throughout, the additional wear at such points is negligible with pantograph pressures as high as 35 lb.

As regards lubrication, while it would of course be desirable to operate without this feature, experience has shown that even with comparatively infrequent service, satisfactory lubrication of contact wires can be maintained, although as stated by Mr. Brown, the contact wires within and in the vicinity of the large yards receive more lubrication, particularly in and near overhead switches. This also applies to curves due to wiping action.

While it is unquestionably true that generally speaking it is desirable to make refinements in pantograph designs as regards weights, lighter pressures, and lower inertias, it is commonly agreed that coordination in the design of both pantograph and overhead is necessary, and there is some question as to whether such coordination is not approached with the relatively higher pantograph pressures in combination with the weight of two wires in the same horizontal plane as compared with the very light pressures and correspondingly light overhead construction as used in some European installations.

Mr. Withington in his discussion very properly emphasizes the desirability of uniformity of suspension for contact wires, that is, the freedom of movement in a vertical plane at all points. By suggestion this of course includes uniformity in weight, which of course cannot be realized on account of the necessity for overhead switches and certain fittings attached to contact wires. From our observation, if the contact wires are free to move in a vertical plane at all points of suspension, the additional wear imposed on contact wire is reduced to a minimum.

As referred to in our paper, with regards to the freedom from burned messengers with loop hangers, we would suggest that in the case referred to, the current demand at locomotive rather than the substation capacity would be the determining factor.

As regards the flexibility of the pantograph shoe mounting, while this of course does not compare with the commonly used European design, either as to delicacy or range, there is no question but that the small amount of movement provided is a valuable asset, particularly with the flexible contact-wire suspension referred to elsewhere.

There is no question but that on some systems contact-wire splicing devices are responsible for considerable trouble in that the designs commonly used enclose the contact wire and offer an obstruction to the collector shoe, which becomes worse as wear on the splicing device increases. A splicing device which permits uninterrupted contact with the wire and is of the minimum weight consistent with the requirements, will do away with this trouble to a large extent. Such a device is available.

Calculation of Stray Load Losses

BY G. H. ROCKWOOD[1]

Enrolled Student, A. I. E. E.

Introduction

QUITE early in the history of the development of the alternating current generator it was recognized that there might be losses present under load conditions in addition to the no-load losses and the armature copper loss due to load current. Because no one had a satisfactory means of measuring this loss it was not included in the early definitions of conventional efficiency. As competition increased and as economic pressure demanded higher and higher efficiences the necessity of approximating this loss was apparent. Accordingly the A. I. E. E. rules were changed to include one-third of the loss under sustained polyphase short circuit.

This rule was short lived for, at the Winter Convention of 1913, papers were presented giving the results of carefully made input-output tests which tended to show that the entire loss on sustained polyphase short circuit should be taken as a measure of the stray load loss for the salient pole alternator. This rule has remained in force and in view of its general acceptance it is to the interest of designers of salient pole alternators to be able to predetermine this loss.

It is the purpose of this paper to present some general methods of attacking the problem. It is not intended that the results should be complete but they are presented simply as a starting point for the attack on this problem.

Proceeding on the principle that a formula cannot be correct unless it has the dimensions of the quantity which it represents or expresses, we may quite readily develop some of our familiar relations. As the complexity of the problems which we treat by this method increases, the difficulties encountered in its application also increase until a point is reached beyond which we cannot go without assistance.

In the case at hand, the calculation of stray load losses, this assistance may come in one of two forms; it may be experimental evidence as to the exponents of certain of the variables, or it may come in the form of assumptions as to the variables involved and the manner of their variation. It is evident, therefore, that the method is not rigorous but is one which will enable us to derive a formula from otherwise incomplete data.

The greatest difficulty encountered in the application of this, or any other, method to the calculation of losses in iron is the fact that we know the loss depends in some manner upon the flux density. But the flux density for any magnetizing force is a complex function of the permeability, a property of the iron which is not constant. Because we have no mathematical expression for the permeability of iron we must make certain assumptions in regard to the behavior of iron under strong magnetizing forces, such as are present in electrical machines. The two most commonly accepted assumptions in regard to permeability are those of constant permeability, or the "limiting value of the density" theory in which it is assumed that there is a maximum possible density. Which assumption will be the better for any given case depends upon the application, but, in general, the assumption of constant permeability is made.

The formulas derived in this manner will require the inclusion of empirical constants. These constants may be determined by statistical methods to be discussed later.

Instead of trying to develop a single formula for the short circuit core loss, it is desirable to separate the total loss into distinct parts and develop formulas for each of these parts separately.

The parts into which it is most conveniently divided are:

1. An eddy current loss in the armature copper.
2. A loss in the stator iron.
3. A pole face loss.
4. An end loss.
5. A loss in the amortisseur winding.

These component parts will be discussed in turn.

Eddy Current Losses in the Armature Copper

Eddy current losses in the armature copper present the source of stray load loss usually recognized in design books. The method of calculating them has usually been to assume that the ohmic resistance of the armature was increased by an amount varying from 10 per cent to 50 per cent. The uselessness of such a method is evident.

In the early days of synchronous machine design when the existence of these losses was not recognized it was not at all uncommon to employ designs such that this loss constituted the major part of the total short circuit loss. It is only within the last five or six years that accurate and easily applicable methods of computing and minimizing this loss have been available. At the present time, however, this loss is rarely over 25 per cent of the total short circuit loss so we see the necessity of obtaining accurate knowledge of the factors on which the remainder of the stray load loss depends if improvements are to be made in the design of salient pole alternators.

There is extensive literature on the subject of eddy

1. Enrolled Student, A. I. E. E., Massachusetts Institute of Technology, Cambridge, Mass.

Presented at the Regional Meeting of Dist. No. 1, at Pittsfield, Mass., May 25-28, 1927.

current losses in the armature copper and there will not be space here to review it. Reference should be made, however, to the work of Prof. W. V. Lyon as given in his A. I. E. E. paper in 1921. It might also be stated that the method given by Mr. I. H. Summers, and based on Prof. Lyon's work, at the 1927 Winter Convention of the A. I. E. E., was used in connection with the work on which this paper was based.

Loss in the Stator Iron

The flux wave form in the air gap of a salient pole alternator under load varies with the power factor at which the machine is operating. This condition renders it extremely difficult to determine the core losses under load. We are seeking, however, to express the core losses at a fixed power factor, and the power factor with which we are concerned is one which gives rise to very special relations, between the main field flux and the armature reaction flux. The power factor which we are to consider is extremely close to zero in a lagging direction.

Since the flux densities under short circuit conditions are not ordinarily found in the usual course of design it will be necessary to determine them before the loss can be computed. It will be convenient to express them as a percentage of the open circuit densities.

If a salient pole alternator operates at zero power factor the axes of the main field flux and the armature reaction flux will coincide. If the power factor is leading the flux waves will add and if the power factor is lagging the net flux will be the difference of the two waves. The wave form of the two fluxes will not be the same, however, so the addition and subtraction mentioned above must be that of harmonics of the same order.

If we are to be able to calculate the flux wave existing in the air gap of a salient pole alternator operated on short circuit at such an excitation that rated current flows in the armature windings we must make certain assumptions. These assumptions are four in number and are given below:

1. That the air gap flux wave consists of four components and four only.
   a. A fundamental due to the main field m. m. f.
   b. A third harmonic due to the main field m. m. f.
   c. A fundamental due to the armature reaction m. m. f.
   d. A third harmonic due to the armature reaction m. m. f.
2. That the four components of the flux wave are determined by the value of the three ratios:
   a. Maximum gap to minimum gap.
   b. Pole arc to pole pitch.
   c. Minimum gap to pole pitch.
3. That the armature reaction m. m. f. has a sinusoidal space distribution.
4. That the machine operates at zero power factor lagging.

Third Harmonic $= A \times B - 0.7$

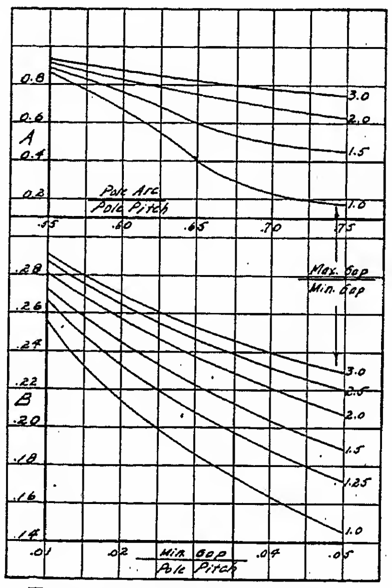

Fig. 2—Third Harmonic of the Air Gap Flux Wave when a Salient Pole Synchronous Machine is Excited only by a Sine Wave Armature m. m. f. whose Axis Coincides with the Pole Center
Third Harmonic $= A \times B$

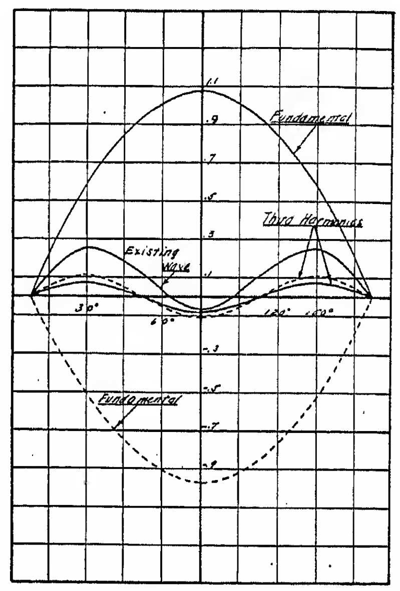

Fig. 3—Graphical Determination of the Zero Power Factor Short Circuit Air Gap Flux Wave

At the winter convention of the A. I. E. E. in 1927, Mr. R. W. Wieseman presented a paper giving curves for the determination of the four components of the short circuit flux wave mentioned above in terms of the three ratios of assumption number two. (See Figs. 1 and 2.) The accuracy of these curves is discussed in the paper and no more need be said about them here.

It will be assumed that these curves give the actual amplitudes of the flux wave components.

Figure 3 shows a graphical combination of the four components to give the existing air gap flux wave and we shall now proceed to develop a method for doing this analytically. The upper half of the figure, in full lines, represents the flux components of the main field. For convenience this has been considered positive and the peak of the actual no-load flux wave, or main field flux wave, has been taken as unity. Since we have zero power factor in a lagging direction the flux armature reaction will subtract from that of the main field so the two dotted components representing this flux have been shown negative. In connection with this plotting it must be remembered that for a salient pole machine the armature reaction flux at zero power factor is always more peaked than a sine wave and so with the convention of plotting here adopted the third harmonic component will always be positive with respect to the main field. A glance at Fig. 1 will show that the third harmonic of main field flux may be either positive or negative. The existing flux wave in Fig. 3 is, of course, the sum of the four components shown in the figure.

Before any addition of components can be made we must find some common basis for their measurement since the curves of Mr. Wieseman's paper give the four components as a per cent of the total wave of either armature reaction or main field flux as the case may be. This common basis is found by expressing the m. m. f. applied under short circuit conditions as a percentage of the m. m. f. required for the air gap. This assumes that an ampere turn on the field is just as effective in producing flux as an ampere turn on the armature. We must determine another constant, however, because the value of the armature reaction as determined by the usual design formula, for three-phase $2.12\ N\ I\ K_p\ K_d$, is based on a time distribution instead of a space distribution. This constant may be found as follows:

I. Assume a winding having all turns concentrated in a single pair of slots.
II. Assume a full pitch winding.
III. Winding to have Z inductors/pole/phase.
IV. I = r. m. s. current/inductor—strictly sinusoidal.

Such a winding would give rise to a rectangular m. m. f. wave having a value of

$$\text{M. M. F.} = \sqrt{2}\, I\, Z/2.$$

The fourier series for such a wave would be

$$Y = 4/\pi\ (\sqrt{2} I Z/2)\ (\sin X + 1/3 \sin 3X + 1/5 \sin 5X + \ldots)$$

We shall now proceed to neglect all terms in this series except the first. In a three-phase winding the third harmonics will cancel, as will all the triplen harmonics, while the fifth, seventh, etc., will move relatively to the pole faces and so induce currents in the pole faces which tend to damp out the flux produced by these harmonics. Our usual formulas give us the height of the rectangular wave represented by the above fourier series. The ratio of the height of this wave to the maximum value of the fundamental of the series representing it is evidently $4/\pi = 1.27$ which is the constant we are seeking.

Making use of this constant the expression for the short circuit air gap density in terms of the open circuit air gap density becomes (for each component):

$$B_1 = B_{nL}\left[A_{1m}\left(X + \frac{A\ R}{F_g}\right) + \frac{1.27\ A\ R\ A_{1a}}{F_g}\right]$$

$$B_3 = B_{nL}\left[A_{3m}\left(X + \frac{A\ R}{F_g}\right) + \frac{1.27\ A\ R\ A_{3a}}{F_g}\right]$$

(The addition is algebraic. For nomenclature see the table of symbols.)

These then are the relations for determining the short circuit air gap density analytically. Similar relations between the amplitudes of the waves made it possible to construct Fig. 3.

The density distribution which has just been described will not obtain in the iron portions of the machine. We may, however, assume that it will give us an indication of the densities in the teeth, especially after the considerations which are now to be presented. If the armature be supplied with current, the field not being excited, the flux due to the armature current will follow a path somewhat as indicated in the figure below.

If the machine be short circuited and the field excited, so as to cause rated current to flow in the armature, there will be set up in the teeth and in the core immediately below the slot the same flux as before. In addition there will be a fundamental flux due to the main field m. m. f. By Lenz's law these two fluxes will be in opposition and, since they must be nearly equal, the difference being that necessary to compensate for armature IR drop and for end leakage drop, their resultant in the core will be negligible and we may neglect the loss in the core due to fundamental flux.

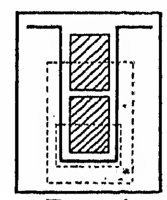

FIG. 4

The fundamental tooth density on short circuit is rarely more than 20 per cent of the open circuit tooth density and so causes not more than 4 per cent of the open circuit tooth loss. As the latter is only about ¼ of the total open circuit core loss we see that the corresponding short circuit core loss is negligible.

The third harmonic density in the armature core will produce a negligible loss, because of the fact that the third harmonic in the core has three times as many poles as does the fundamental, so we may neglect the loss due to this component of flux.

The only component which we need consider is the third harmonic in the teeth. This will be expressed by an equation similar to that given on page 2, except that B_{nL} will be replaced by the no-load tooth density. The loss will then be:

$$W_t = K_1 K_i K_f \frac{\text{volume of teeth}}{1000} w_3.$$

w_3 = loss per cubic inch in standard material at standard triple frequency corresponding to density B_3.

To calculate the triple frequency core loss in the armature teeth for the condition of sustained polyphase short circuit it is, therefore, necessary to compute the third harmonic tooth density as a percentage of the open circuit tooth density and to then obtain the loss from the usual laboratory loss curves.

Short Circuit Pole Face Loss

Under sustained polyphase short circuit the current carried by each slot will give rise to an m. m. f. which will cause flux pulsations in the pole face. The magnitude of the loss produced will be a function of these tooth frequency flux pulsations. Since the path of this flux is largely in air we may assume, as a first approximation, that it is directly proportional to the m. m. f. producing it. This m. m. f. will be proportional to the current per slot, which, for any given machine, will be proportional to the ampere turns per inch of armature periphery. It so happens that the ampere conductors per π-inch of periphery are numerically equal to the ampere turns per inch of armature periphery at 77 per cent pitch. It will thus be convenient, and sufficiently accurate for any practical value of the pitch, to express the flux as proportional to the ampere conductors per π-inch of armature periphery.

To derive a formula for the short circuit pole face loss use has been made of a similar study of open circuit pole face losses. The method used was that of a dimensional analysis, starting with experimental evidence as to the best values of the exponents for certain of the variables. (See Appendix A.) As regards short circuit pole face loss, however, we have no experimental evidence on which to base a dimensional analysis so the following reasoning is proposed.

Under the assumption of constant permeability the exponent of stator slot pitch was found to be unity, a value lower than that indicated by the most reliable experimental evidence. The limiting value of the density theory gave rise to an exponent for the stator slot pitch of two, but it also involved the tooth frequency to the second power when experimental evidence and the conventional theory alike would indicate the one and one-half power. In both of these derivations for the open circuit condition the same basic assumptions were made. It was finally decided to use a form which was not dimensionally correct, but which involved the tooth frequency to the one and one-half power and the stator slot pitch to the second power, the other exponents being those in agreement with dimensionally correct formulas.

In formulating the short circuit pole face loss it seems desirable to use the formula developed for open circuit core loss, substituting a quantity which shall be proportional to the short circuit flux producing the pole face loss in place of the air gap density used in the open circuit form. It was something of a question as to whether or not the ampere conductors per slot should be used instead of the ampere turns per inch of periphery as outlined above. It will be noticed that the use of the ampere conductors per slot would necessitate involving the stator slot pitch to the fourth power. This exponent is so much higher than any given by experimental work or by the dimensional analysis that it seems better to use the ampere turns per π-inch of periphery as being proportional to the flux than to use the ampere conductors per slot.

The final form of the short circuit pole face loss formula will then be:

$$W_p = K_2 (16\,t) \left(\frac{H \times \tau_0}{100}\right)^2 \frac{P A}{1000} \left(\frac{V}{10\,g}\right)^{15}$$

End Loss

Under sustained polyphase short circuit conditions the windings carrying current are linking the end fingers, clamping flanges and armature binding bands, thus inducing eddy currents in all of these portions of the machine. In addition there will be a considerable leakage flux from the end connections of the machine, some of which may get into the frame, end shields, and various other stationary portions. It is understood, of course, that this flux of the armature winding which is producing end loss is revolving at synchronous speed, in consequence of the polyphase nature of the winding which produces a revolving field.

If we are to be able to compute the loss we must first compute the leakage flux producing the loss. This may be done by multiplying the m. m. f. by the permeance of the leakage flux path. The m. m. f. will, of course, be the ampere turns of armature reaction, or some fraction thereof. In Appendix B is a dimensional derivation of a formula for end loss.

It now remains to find an expression for the permeance of the leakage flux path. If we assume that the adjacent masses of iron may be neglected we see, from Appendix C, that the permeance is of the form:

$$C = \mu \times \text{pole pitch} \times \text{coil pitch}.$$

Making the assumption of constant permeability and using the formula derived in Appendix B our end loss formula becomes:

$$W_e = K \times \text{pole pitch} \times \text{coil pitch}\, P\, V \sqrt{f}\, (A\, R)^2.$$

But the number of poles times the pole pitch is equal to gap diameter times a constant, whence:

$$W_e = K_3 \frac{D\, V \sqrt{f}}{1000} \left(\frac{A\, R}{10{,}000}\right)^2 \times \text{coil pitch}.$$

Loss in the Amortisseur Windings

Thus far we have assumed that the armature reaction m. m. f. was sinusoidally distributed about the periphery. With a finite number of phases this can never be exactly true, but for the losses thus far considered the approximation has been close. There is, however, a loss

due to the fact that the armature reaction m. m. f. is not sinusoidal. The wave form of the armature reaction m. m. f. will be determined by the pitch of the winding and by its arrangement in the slots. For our present purpose the effect of pitch alone will be considered. The arrangement of the winding will, in many cases, be more important but it is the present purpose to produce a formula which shall be comparatively simple to apply in a specific case rather than to obtain one which gives greater accuracy at the cost of greatly increased labor.

If the pitch is such that the wave form is not sinusoidal there will be certain of the higher harmonics which will move relatively to the pole faces. The triplen harmonics will cancel in the three-phase machine leaving all others to produce loss. Of these the fifth and seventh are the most important.

To determine the loss due to these flux harmonics it is necessary to find the current induced in the amortisseur winding by each of these harmonics and then to find the loss due to this current, taking into consideration the effective resistance of the rotor bars. Such a procedure is, of course, far too complicated for the case at hand and a simple approximation must be sought.

If we recognize the fact that, as far as this loss is concerned, the synchronous machine may be treated by an equivalent circuit exactly similar to that for the single-phase induction motor we may arrive at the desired approximation. By the use of this circuit we may deduce an expression for the loss in the bar windings of the rotor as some function of the stator coil pitch. (Appendix D.) To determine the form which this function will take we must remember that the flux harmonics due to the arrangement of the winding will also produce a leakage reactance drop in the phase belt. This reactance is easily calculable for the induction motor and we may simply use values taken from such a curve for the values of this function of coil pitch. This apparent mixing of the units of loss and reactance is not real since the units are proportional and we shall have to prefix this expression for the loss by a constant to be determined by statistical methods.

A dimensional check of the formula was also made and it was shown to be dimensionally correct. In its final form it is:

$$\text{Loss in bars} = K_4 \left(\frac{A\,R \times P}{100{,}000} \right)^2 \frac{L}{D} \times Q \times K_\rho .$$

Q is the function of coil pitch referred to above and K_ρ depends for its value upon the type of amortisseur winding.

Determination of the Values of the Proportionality Constants

Each of the terms in the formula for short circuit core loss has been preceded by a coefficient. These coefficients have been included because the formulas as developed are not rigorous and they must be determined from considerations derived from the theory of probability. In determining their values we seek to find the most probable value for each one of the four coefficients. Statistical theory indicates that the most probable value of any observed quantity is that which makes the sum of the squares of the deviations of a set of observations, or a group of such sets, a minimum. In accordance with this theory the method of least squares may be applied for the determination of the values of the co-efficients.

For the purpose of determining these values the loss as given by the formula was computed for some 150 machines of various types and ratings. The expression for the loss including the unknown coefficients was then equated to the loss as determined by test and the method of least squares applied to find the separate values.

The method of least squares results in a number of "normal equations" equal to the number of unknowns. These equations are to be regarded as linear simultaneous equations and have to be solved. Unfortunately the coefficients of these "normal equations" are usually such as to require special methods of solution if proper values are to be obtained. Probably the simplest and best method for solving them is that due to Gauss and known as the method of Gauss. (See Whitaker & Robinson, "The Calculus of Observations.")

In applying the method of least squares in this particular investigation the computation of the eddy current loss in the armature copper should be assumed to be without error.

Accuracy of the Formula

In using any formula such as this the designer of electrical machinery is interested not only in the error inherent in the formula but the probable error of the result. If the results of using this formula be plotted as a frequency distribution, *i. e.*, per cent error in each individual case against the number of times it occurs, the usual normal distribution or probability curve will result. The fact that we have such a frequency distribution is the thing of greatest interest to the designer. Associated with such a distribution are a number of means intended to give a reliable index of the accuracy of the result.

This normal distribution curve is completely defined by certain parameters, one of which is the so-called standard deviation, or σ. This value of σ happens to be one-half the distance between the points of inflection of the normal distribution curve. The standard deviation may be found from the following relation:

$$\sigma = \sqrt{\frac{\Sigma\ (x)^2}{N}}$$

where x is any deviation from the average and N is the total number of entries. This is, of course, simply the root mean square deviation.

The probable error is defined to be such that the chances are even whether the deviation exceeds it in

absolute magnitude or is less than it. If this be denoted by the symbol Q we have:

$$Q = 0.67449\ \sigma.$$

The computation of the value σ requires considerable labor. Fortunately there is a constant relation between the value of σ and the mean deviation which is obtained by considering all deviations as positive and taking their average. Thus the probable error and the mean deviation differ only by a constant and we may use the mean deviation as a measure of the accuracy of the formula. The relation is, then:

$$Q = 0.8345 \text{ mean deviation.}$$

The usual manner of measuring the accuracy of such a formula is to form the ratio

$$\frac{\text{Test core loss}}{\text{Calculated core loss}}$$

for each application and to perform the above computations with this average. When dealing with stray load losses as determined by the sustained polyphase short circuit test, however, it is more convenient to express the error as a percentage of the copper loss at full load current. This is done for several reasons. First, it has been experimentally shown that the stray load loss, or short circuit loss, varies with the square of the current as does the copper loss and so it is natural to treat it in the same manner. Secondly, it has been the practise of designers from time immemorial to estimate this loss by assuming it to be a percentage of the copper loss at rated current. We shall, therefore, be measuring the accuracy of the formula in a unit which is already understood by those who are to use the formula. Finally it is desirable to minimize the testing errors which are greatest where the loss is but a small part of the copper loss.

Measuring the accuracy of the formula for its application to the above mentioned 150 machines the results were as follows:

Mean deviation.............	27.5 per cent
Average per cent error.......	10.9 per cent
Maximum per cent error	
Plus....................	41.2 per cent
Minus.................	41.5 per cent

The above per cent errors are expressed as a per cent of the full load copper loss.

The sources of error in the formula are chiefly due to the effort to apply a single formula, not in itself complete, to a large number of machines of different construction. A second source of error which is of considerable importance lies in the fact that the effect of the coil grouping has been omitted in computing the loss in the amortisseur windings.

Finally it must be pointed out that the accuracy of the experimental determination of this loss, thus far assumed to be without error, is not all that could be desired. In measuring the short circuit loss, as per the A. I. E. E. rules, it is necessary to deduct from the measured input not only the friction and windage but the armature copper loss as well. The ohmic resistance is to be used in this computation but it must, of course, be measured at a temperature corresponding to that obtaining in the armature windings when the loss was measured. This is not always known, so some temperature has to be assumed and consequently a quite appreciable error is introduced. Finally the loss we are seeking to determine is not capable of direct measurement but is a measured loss minus other more or less accurately determinable losses.

In this work the point most worthy of note is the recognition of stray load losses other than the armature eddy current losses. In recognizing these other losses and in formulating an expression for them a method has been advanced for determining the tooth densities of both fundamental and third harmonic components of the flux wave actually existing under zero power factor short circuit conditions.

Emphasis should be laid upon the fact that the dimensional theory and statistical methods have played the major role in all the work which has been here presented. The results cannot be claimed to be without error nor are they entirely novel, but it is believed that new light has been thrown on the subject of core losses in salient pole alternators and that the formulas of the type described here have wide application.

The writer wishes to express his indebtedness to Mr. P. L. Alger, for his constant interest in the work and for his many helpful suggestions.

Appendix A

The material of this appendix refers primarily to the problem of the calculation of open circuit pole face loss, the application of this work to the problem of pole face loss having been shown in the body of the paper.

An effort has been made to be guided by the work of previous investigators. In 1909, C. A. Adams gave the first noteworthy theoretical discussion of the subject in this country. He proposed the following:

$$W_p = \frac{3.3\,P\,A}{10^7}\,t\,B_0^2\sqrt{\frac{V^3}{\mu\,p\,\tau_0}}$$

(B_0 dependent upon slot width/effective gap)

which it will be noted, involves tooth frequency and slot pitch to the 1.5 power.

In 1916, F. W. Carter proposed the following theoretical formula:

$$W_p = \frac{\pi}{24}\,F\,(s/g)^{1.5}V^{1.5}B^2\sqrt{\frac{1}{\mu\,p}}$$

All other theoretical formulas seem to be special cases of one or the other of the above, *i. e.*, applicable to special types of machines only.

Many special formulas based on experimental work have been proposed. The first of these was by Wall and

Smith in 1908. Their work applied only to a single machine and so does not include the lamination thickness. They gave:

$$W_p = K\,P\,A\,B^{2.1} f_t^{1.5} (s/g)^{3.5}.$$

In 1909 Adams gave the following based on experimental work:

For 0.06″ laminations:

$$W_p = \frac{4.62\,P\,A}{10^4}\left(\frac{B}{10^{-4}}\right)^{2.4}\left(\frac{V}{10}\right)^{1.55}(s/g)^{1.5}\frac{1}{\sqrt{\tau_0}}.$$

For 0.014″ laminations:

$$W_p = \frac{3.15\,P\,A}{10^4}\left(\frac{B}{10^{-4}}\right)^{2.3}\left(\frac{V}{10}\right)^{1.55}(s/g)^{1.22}\frac{1}{\sqrt{\tau_0}}.$$

Probably the most reliable experimental work is that of Spooner and Kinnard in 1924. They gave a separate formula for each thickness of lamination, but the exponents were practically the same for all thicknesses. Their formula was:

$$W_p = K\,B^{2.6} f_t^{1.6} (s/g)^{2.2}\,\tau_0^{1.3}\,P\,A.$$

Laminations	*Value of K*
0.0281″	.56
0.0625″	1.2
0.125″	2.6

The above table corresponds to including t with an exponent slightly greater than unity.

In this investigation it is proposed to develop a new formula by means of a dimensional analysis which shall make use of the results just summarized. It seems highly probable that the exponent of flux density should be two, the larger value given by the experimental work probably being due to the unavoidable inclusion of losses other than pole face loss, end loss, and tooth pulsation loss, for example.

In making a dimensional study we are confronted with the fact that we have no mathematical expression for permeability as a function of density. We may, however, assume constant permeability, *i. e.*, a straight line magnetization curve, or we may make use of the so-called limiting value of the density theory. This assumes an infinite permeability up to a certain point and zero permeability thereafter. A dimensional analysis by each method follows.

B = air gap density.
f_t = tooth frequency.
τ_0 = stator slot pitch.
t = lamination thickness.
μ = permeability of pole iron.
ρ = resistivity of pole iron.
B_{sat} = saturation value of density.

Constant permeability theory

$$\text{Watts/square inch} = K\,B^a f^c \tau_0^d t^e \mu^g \rho^h.$$

Dimensionally

$$M\,T^{-3} = L^{-\frac{a}{2}} M^{\frac{a}{2}} T^{-a} \mu\, T^{-c} L^d L^e \mu^g L^{2h} T^{-h} \mu^h.$$

$$\begin{aligned} \text{Solving for } L\,0 &= -a/2 + d + e + 2h \\ M\,1 &= a/2 \\ T - 3 &= -a - c - h \\ \mu\,0 &= a/2 + h + g. \end{aligned}$$

Whence $a = 2$ and:

$$\begin{aligned} 1 &= d + e + 2h \\ 1 &= c + h \\ -1 &= g + h \end{aligned}$$

Taking $c = 1.5$ from the work of Carter and Spooner
Using $e = 1$ from Spooner's work
$h = 1.5$
$g = -0.5$.
$d = 1$.

Limiting value of the density theory

$$\text{Watts/square inch} = KB^2 f_t^c \tau_0^d t^e \rho^h B_{sat}^m.$$

Dimensionally

$$MT^{-3} = L^{-1} M \mu T^{-2} T^{-c} L^d L^e L^{2h} T^{-h} \mu^h L^{-\frac{m}{2}} M^{\frac{m}{2}} T^{-m} \mu^{\frac{m}{2}}$$

$$\begin{aligned} \text{Solving for } L\,0 &= -1 + 2h - m/2 + d + e \\ M\,1 &= 1 + m/2 \\ T - 3 &= -2 - c - h - m \\ \mu\,0 &= h + m/2 + 1. \end{aligned}$$

$$\begin{aligned} \text{Whence}\quad m &= 0 \\ h &= -1 \\ c &= 2 \\ d + e &= 3. \end{aligned}$$

From Spooner and Kinnard's work:

$$e = 1$$
$$d = 2.$$

The constant permeability theory gives rise to an exponent for τ_0 lower than that found by experiment, while the saturation value of the density theory gives rise to a value a little above the usual experimental values and an exponent of frequency which is too high, both by theory and experiment, for this relatively high frequency loss. It was, therefore, decided to use the exponents as given by the constant permeability method, except that the exponent of τ_0 would be taken as 2.0.

Shape constants such as s/g which enter as ratios cannot be handled by this method, so we shall have to include them with exponents derived from experimental work. The best value for the exponent of s/g seems to be 1.5.

As derived above the formula is in terms of watts per square inch of pole face area, so to get it in terms of kilowatts for the machine we must multiply by $P\,A/1000$ whence our final result will be:

$$W_p = K\,(16\,t)\left(\frac{B\,\tau_0}{100}\right)^2 \frac{P\,A}{1000}\left(\frac{V}{10\,g}\right)^{1.5}.$$

Appendix B

Assuming that end loss is a function of the ampere turns of armature reaction (per pole), the permeance of the leakage flux path, the line frequency, the pole pitch,

the permeability, and resistivity of the stator iron we may proceed as follows:

C = permeance of leakage flux path.
$A\,R$ = ampere turns of armature reaction per pole.
$p\,p$ = pole pitch.
P = number of poles.
f = line frequency.
V = peripheral velocity.
ρ = resistivity of stator iron } assumed constant.
μ = permeability of stator iron }

Watts $= K\,C\,P\,f^n\,(A\,R)^2\,p\,p^m\,\mu^r\,\rho^s$.

Dimensionally

$$L^2\,M\,T^{-3} = L\,\mu\,T^{-n}\,L\,M\,T^{-2}\,\mu^{-1}\,L^m\,\mu^r\,L^{2s}\,T^{-s}\,\mu^s.$$

Solving for L $\quad 2 = 1 + 1 + m + 2\,s.$
$M \quad 1 = 1$
$T \quad -3 = -n - 2 - s$
$\mu \quad 0 = 1 - 1 + r + s.$

Assuming $s = -0.5$, since for a high frequency loss ρ enters to the minus 1/2 power

$$2 = 1 + 1 + m - 1$$
$$-3 = -n - 2 + .5$$
$$0 = 1 - 1 + r - .5$$

whence

$$m = 1$$
$$n = 1.5$$
$$r = .5.$$

But $V = 5\,f\,(p\,p)$.

So we may write:

$$W_e = K\,\frac{C\,P\,V\,\sqrt{f}}{1000}\left(\frac{A\,R}{10{,}000}\right)^2.$$

Appendix C

Since we are to neglect the effect of the adjacent masses of iron the permeability of the leakage flux paths will be that of air. The flux may then be considered as that due to an air core solenoid of length equal to the "effective length" of the end connections. Below is given a development of one end of the armature winding. Each turn of such a winding may be represented as below, one-half only being considered, since from symmetry we need only multiply by two to obtain final results.

If we consider this figure to represent one-half of a single turn we see that there will be four components of m. m. f. produced by the current. These components are.

$$F_1 = \frac{.4\,\pi}{4}\cos\alpha \qquad F_3 = \frac{.4\,\pi}{4}\sin\alpha$$

$$F_2 = \frac{.4\,\pi}{4}\cos\alpha \qquad F_4 = \frac{.4\,\pi}{4}\sin\alpha.$$

Evidently F_3 and F_4 will cancel at zero pitch, and in all cases their resultant will be small at low pitches, so as an approximation the net m. m. f. $= \dfrac{.4\,\pi}{2}\cos\alpha$.

If we now have a coil consisting of N turns, each carrying a current of I amperes, the net m. m. f. will be:

$$F = \frac{.4\,\pi}{2}\,N\,I\cos\alpha.$$

The flux will be (for both ends):

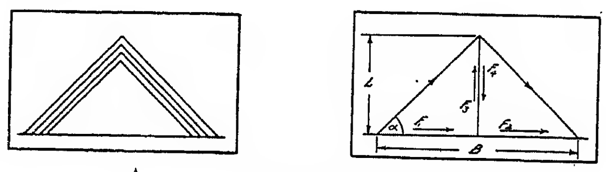
$$\phi = \frac{.4\,\pi\,N\,I\cos\alpha}{R}$$

$$R = \frac{L}{\mu\,A} = \frac{L}{\mu\,\pi\,r^2} \text{ where } r = \text{radius of core}$$

$$\phi = \frac{.4\,\mu\,\pi^2\,r^2\,N\,I\cos\alpha}{L}.$$

If we had had a uniformly wound air core solenoid of the same diameter,

$$\phi' = \frac{.4\,\mu\,\pi^2\,r^2\,N\,I}{L'}.$$



A B

Fig. 5

Suppose the two solenoids were of the same length. Then $L = L'$ and $\phi/\phi' = \cos\alpha$, or the effective length of the end connections is:

$$L_{\text{eff}} = L\cos\alpha.$$

This effective length is, then, a measure of the permeance of the leakage flux path.

The value of α will be determined by the spacing between coils necessary to give the proper insulation for the voltage rating of the machine. Its value does not vary greatly, however, so we may assume it constant. The permeance may then be expressed as:

$$C = \mu \times \text{pole pitch} \times \text{coil pitch}.$$

Appendix D

In, so, far as the loss in the amortisseur windings is concerned a synchronous machine may be treated by an equivalent circuit exactly similar to that for the single-phase induction motor. The secondary circuit will be composed of two parts: the usual resistance and reactance where the resistance is expressed by $R_2/s = \infty$, since the machine is operating at synchronous speed, and a second portion which involves the reactance for the nth harmonic. In parallel with this secondary circuit will be the magnetizing circuit, having a reactance corresponding to that for the nth harmonic.

Below is given a diagram of the equivalent circuit which we are considering.

It will be noticed that the total current carried by the primary divides, part passing through the magnetizing reactance and the remainder through the secondary impedance. The division of this current will, of course, be inversely proportional to the impedances of the two parallel paths, but that current which passes through the magnetizing circuit produces no loss. This division of current might be expressed by setting the total current equal to $1 + X_m/X_2$. X_2 is the secondary, or rotor, reactance, which for open slots is approximately 10 per cent, for closed slots it may be as high as 40 per cent. Consequently this loss will be changed from what it would be if all the current passed through X_2 in the ratio of $(1 + X_m/X_2)^2$. Putting in the values which were given above this is:

$$\left.\begin{array}{l}(1/1.1)^2 \text{ for open slots} \\ (1/1.4)^2 \text{ for closed slots}\end{array}\right\} \left\{\begin{array}{l}\text{for important harmonics} \\ \text{such as fifth and seventh.}\end{array}\right.$$

Or, for our two extreme cases the variation might be that from 0.8 to 0.5, a variation which may be neglected.

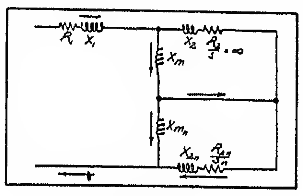


FIG. 6

Assuming that the loss is wholly an $I^2 R$ loss in the rotor bars we may derive the formula as follows:

For current of any given harmonic

$$k\, I^2 = k\, (A\, R)^2$$

$$A\, R = \frac{2.12\, N\, I\, K_p\, K_d}{P}$$

$$k = \frac{P^2\, (A\, R)^2}{(N\, K_p\, K_d)^2} \int (c\, p)\,.$$

The resistance of an induction motor secondary is given by:

$$R_2 = \left(\frac{N\, K_p\, K_d}{1000}\right)^2 \times \frac{\text{Bar length}}{\text{Total section}}.$$

(The resistance of the end rings is neglected since the number of poles is large for the harmonics.)

The total section of rotor bars may be replaced by the square inches of bar section per inch of periphery times the diameter D. The square inches of bar section may be taken as constant. In reality it will be slightly greater for large machines, due to the increased diameter of the bars, but, due to the high frequency of the currents, skin effect will increase the resistance of the bars, or tend to give them an apparently smaller section. Thus we may write:

$$R_2 = K_{pn}^2\, K_{dn}^2\, N^2\, \frac{L \times P}{c\, D}$$

and the loss will be

$$W = K\, (A\, R)^2\, \frac{L\, P_\rho}{c\, D} \int (c\, p)$$

or

$$W = K_4 \left(\frac{A\, R \times P}{100{,}000}\right)^2 \frac{L}{D} \times Q \times K_\rho.$$

Following is a dimensional check of the above.

In the above formula c has the dimensions of length, since it represents the square inches of bar section per inch of periphery.

Expressed in dimensional units:

$$L^2\, M\, T^{-3} = L\, M\, T^{-2}\, \mu^{-1}\, L\, L^2\, T^{-1}\, \mu\, L^{-1}\, L^{-1}.$$

Solving for (L)	$2 = 1 + 1 + 2 - 1 - 1 = 2$
Solving for (T)	$-3 = -2 - 1 = -3$
Solving for (M)	$1 = 1$
Solving for (μ)	$0 = -1 + 1 = 0.$

Hence the formula is dimensionally correct.

TABLE OF SYMBOLS

- A_{1m} amplitude of fundamental of main field flux wave.
- A_{3m} amplitude of third harmonic of main field flux wave.
- A_{1a} amplitude of fundamental of armature reaction flux.
- A_{3a} amplitude of third harmonic of armature reaction flux.
- X armature leakage reactance expressed as a decimal.
- B_{nh} no-load air gap flux density.
- B_3 short circuit third harmonic density.
- $A\, R$ armature reaction ampere turns per pole.
- F_g air gap ampere turns per pole.
- K_i constant dependent upon quality of stator iron.
- K_f constant dependent upon frequency.
- w_3 loss per cubic inch in standard iron at standard frequency at density B_3.
- t thickness of pole laminations.
- H armature reaction per π-inch.
- τ_0 stator slot pitch.
- P number of poles.
- A area of air gap under one pole.
- V peripheral velocity in thousands of feet per minute.
- g effective air gap.
- D gap diameter in inches.
- L length of rotor stacking in inches.
- Q a factor dependent upon coil pitch.

Proximity Effect in a Seven-Strand Cable

BY J. E. L. TWEEDDALE[1]

Enrolled Student, A. I. E. E.[1]

THE calculation of the alternating current resistance ratio due to skin effect or proximity effect has been worked out for many shapes and combinations of conductors but often without recourse to experimental results. It is, accordingly, the purpose of this work to check calculations with tests for the type of calculation recently developed, covering the losses in several round wires connected in parallel, of which the arrangement is such that unequal currents flow in the different wires. The experimental results with which the calculated results are to be compared are those presented by A. E. Kennelly and H. A. Affel[2] in 1916 for seven-strand cables. Their work covered radio frequencies up to 100,000 cycles in rather small conductors. The derivations as presented here are applicable to all frequencies and sizes of conductors.

The method of attack is the same as that employed by Dr. H. B. Dwight of the Massachusetts Institute of Technology in the solution of the proximity effect in other arrangements of conductors. The writer wishes to acknowledge the aid and help of Dr. Dwight in the solution of this problem.

In a seven-strand conductor, inequalities of current exist in the separate wires of the conductor. If the return conductor is assumed to be at a distance such that its proximity effect is negligible then we have two unknown currents existing in the seven-strand conductor; *i. e.*, the outer concentric conductors will all carry equal currents I_1 and the center conductor will carry a current I_2 so that the total current $I = 6 I_1 + I_2$.

The effect of spiraling of the wires has been neglected in this calculation. While the wires of a cable are spiraled, the test with which this calculation is to be compared, illustrated in Figs. 4 and 5, was made on seven straight, unspiraled round wires.

The method of attack is in the main as follows: The current density in a single isolated round wire is given by the following expression:

$$i_{r\theta} = \frac{I_1}{\pi a^2} \frac{j \alpha a}{2} \frac{J_0 (j \alpha r)}{J_1 (j \alpha a)} \text{ absamps./sq. cm.} \qquad (1)$$

where r and θ are the polar coordinates of any point in the section of the wire, where

I_1 = total current in the wire

a = radius of the wire

$$\alpha = \sqrt{\frac{j \omega 4 \pi}{\sigma}}$$

$\omega = 2 \pi \times$ frequency

σ = resistivity of material of conductor

and $j = \sqrt{-1}$.

Absolute electromagnetic units are used throughout. The quantity $J_0 (j \alpha r)$ is a Bessel function of the first kind, zero order and argument $j \alpha r$. This can be expressed as an algebraic series but is readily evaluated from tables in which $J_0 (b j \sqrt{j}) = u_0 + j v_0$, where $j \alpha r = b j \sqrt{j}$. The above equation, (1), is based on the fact that the impedance drops at every section of the wire are equal.

The next point is to obtain the effect of the current in the other wires on the distribution of the current in the first wire. It has been shown by Manneback[3] that a current I_2 flowing in an infinitesimal wire will cause a circulating current to flow in a wire of radius a

FIG. 1—ROUND WIRE AND INFINITESIMAL WIRE

at an axial distance s whose current density will be

$$i_{r\theta} = \frac{I_2}{\pi a^2} j \alpha a \sum_{n=1}^{n=\infty} \frac{a^n}{s^n} \frac{J_n (j \alpha r)}{J_{n-1} (j \alpha a)} \cos n \theta \qquad (2)$$

J_n represents a Bessel function of the first kind of order n.

The effect of the current distribution given by (2) is that the impedance drops at every section of the wire are equal. The total current in the wire, obtained by adding up expression (2) over the entire section of the wire, is zero. Since the above two conditions are satisfied, the current density given by (2) can be added to that given by (1) without changing the total current I_1. The necessary condition of equal impedance drops at every section of the wire is still met. The sum of (1) and (2) therefore gives the current distribution in a wire carrying current I_1, and with a concentrated current I_2 near it. Other expressions of the same form as (2) may be added for all the other concentrated alternating currents which may be near the wire.

Now, returning to the seven-strand cable we see that

2. "Skin-Effect Resistance Measurements at Radio Frequencies up to 100,000 Cycles per Second," by A. E. Kennelly and H. A. Affel. Proc. Inst. of Radio Engineers, May, 1916, and *Research Bulletin* No. 13, Mass. Institute of Technology.

Presented at the Regional Meeting of Dist. No. 1, Pittsfield, Mass., May 25-28, 1927.

3. Equation (19), "An Integral Equation for Skin Effect in Parallel Conductors," by Charles Manneback. *Journal of Math. and Physics*, April, 1922, and *Research Bulletin* No. 30, Mass. Institute of Technology.

if we are considering wire A, the proximity effect of the other six conductors must be taken into account. The first step is to assume conductors B, C, D, E, F, and G as infinitesimal conductors. The resultant current density in wire A will be the sum of equation (1) plus the respective terms for the other conductors similar in form to equation (2).

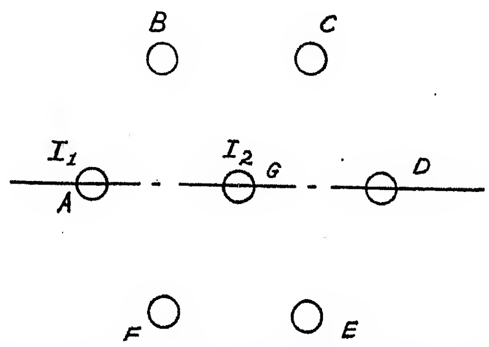

FIG. 2—SEVEN WIRES ARRANGED IN CABLE FORM

The resultant expressions will be, then, as follows:

$$i_{r\theta} = \frac{I_1}{\pi\, a^2} A_0 J_0 (j\, \alpha\, r) + \sum_{n=1}^{n=\infty} A_n J_n (j\, \alpha\, r) \cos n\, \theta \quad (3)$$

and

$$i_{u\gamma} = \frac{I_2}{\pi\, a^2} A_0 J_0 (j\, \alpha\, u) + \sum_{n=1}^{n=\infty} F_n J_n (j\, \alpha\, u) \cos n\, \gamma, \quad (4)$$

etc.,
where A_0, A_n, and F_n are coefficients which for this derivation are as follows:

$$A_0 = \frac{j\, \alpha\, a}{2\, J_1 (j\, \alpha\, a)}. \quad (5)$$

$$A_n = \frac{I_2}{\pi\, a^2}\, j\, \alpha\, a \frac{a^n}{s^n} \frac{1}{J_{n-1} (j\, \alpha\, a)} + \frac{I_1}{\pi\, a^2} \frac{a^n}{s^n} \frac{j\, \alpha\, a}{J_{n-1} (j\, \alpha\, a)} \left[2 \cos \frac{n\, \pi}{3} + \frac{2}{(\sqrt{3})^n} \cos \frac{n\, \pi}{6} + \frac{1}{(2)^n} \right]. \quad (6)$$

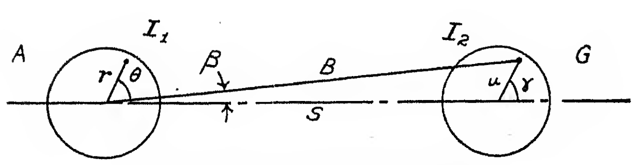

FIG. 3—TWO ROUND WIRES

$$F_n = \frac{I_1}{\pi\, a^2} \frac{a^n}{s^n} \frac{j\, \alpha\, a}{J_{n-1} (j\, \alpha\, a)} \left[\cos n\, \pi + 2 \cos \frac{2\, n\, \pi}{3} + 2 \cos \frac{n\, \pi}{3} + 1 \right]. \quad (7)$$

The expressions (3) and (4) are, therefore, the current densities due to uniform current densities in the others, and I_1 and I_2 in the wires themselves.

The next step is to find the current in each wire due to the A_0 and A_m or F_m currents in the others. For simplicity, let us consider just two of the wires as in Fig. 2, A and G, for the present, to show the method.

Let there be a current density in A in addition to the uniform current density

$$i_{r\theta} = -\frac{I_1}{\pi\, a^2} + \frac{I_1}{\pi\, a^2} A_0 J_0 (j\, \alpha\, r) + \sum_{m=1}^{m=\infty} A_m J_m (j\, \alpha\, r) \cos m\, \theta \quad (8)$$

and likewise for G

$$i_{u\gamma} = -\frac{I_2}{\pi\, a^2} + \frac{I_2}{\pi\, a^2} A_0 J_0 (j\, \alpha\, u) + \sum_{m=1}^{m=\infty} F_m J_m (j\, \alpha\, u) \cos m\, \gamma\, . \quad (9)$$

Each of these integrated over its section will be zero.

Then, the nth term of $i_{r\theta}$ due to $i_{u\gamma}\, u\, du\, d\gamma$ in G is as follows:

$$i_{u\gamma} \frac{j\, \alpha\, a}{\pi\, a^2} \frac{a^n}{B^n} \frac{J_n (j\, \alpha\, r)}{J_{n-1} (j\, \alpha\, a)} \cos n\, (\theta - \beta)\, u\, du\, d\gamma \quad (10)$$

where B and β are variables given by a series for each wire.

$$\frac{\cos n\, \beta}{B^n} = \frac{1}{s^n} \left[1 + \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\, \underline{|k}} \frac{u^k}{s^k} \cos k\, (\gamma - \pi) \right] \quad (11)$$

and

$$\frac{\sin n\, \beta}{B^n} = \frac{1}{s^k} \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\, \underline{|k}} \frac{u^k}{s^k} \sin k\, (\pi - \gamma)\, . \quad (12)$$

The proof of the two preceding expressions is given by H. L. Curtis.[4]

Substituting expression (9) in (10), expanding the difference of the angles, and substituting their respective values from (11) and (12), the nth term of $i_{r\theta}$

$$\left[-\frac{I_2}{\pi\, a^2} + \frac{I_2}{\pi\, a^2} A_0 J_0 (j\, \alpha\, u) + \sum_{m=1}^{m=\infty} F_m J_m (j\, \alpha\, u) \cos m\, \gamma \right]$$

4. H. L. Curtis, Scientific Paper No. 374 of the Bureau of Standards, Washington, D. C., 1920.

$$\left[\frac{j\,\alpha\,a}{\pi\,a^2}\;\frac{a^n}{s^n}\;\frac{J_n\,(j\,\alpha\,r)}{J_{n-1}\,(j\,\alpha\,a)}\right]\left\{\cos n\,\theta\left[1 + \sum_{k=1}^{k=\infty}\frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}}\;\frac{u^k}{s^k}\cos k\,(\gamma-\pi)\right]\right.$$

$$\left. + \sin n\,\theta\left[\sum_{k=1}^{k=\infty}\frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}}\cdot\frac{u^k}{s^k}\sin k\,(\pi-\gamma)\right]\right\}u\,du\,d\gamma. \qquad (13)$$

The above expression is then integrated between the limits 0 to 2 π and 0 to a. The sine term will become zero upon integration and drop out, and likewise

$$\int_0^a\left[-\frac{I_2}{\pi\,a^2}+\frac{I_2}{\pi\,a^2}\,A_0\,J_0\,(j\,\alpha\,u)\right]u\,du = 0.$$

Thus there is left the integral of the nth term of the terms in m which is

$$\sum_{m=1}^{m=\infty}\frac{a^{m+n}}{s^{m+n}}\;\frac{J_{m+1}\,(j\,\alpha\,a)}{J_{n-1}\,(j\,\alpha\,a)}\left[\frac{\underline{|n+m-1}}{\underline{|n-1}\,\underline{|m}}\right]$$

$$[F_m\cos m\,\pi]\,J_n\,(j\,\alpha\,r)\cos n\,\theta\,. \qquad (15)$$

Let B_n be the coefficient of $J_n\,(j\,\alpha\,r)\cos n\,\theta$.

Now let there be an additional current density in A as represented by the expression (15). The resulting current in A due to this additional current is given by

$$C_n\,J_n\,(j\,\alpha\,r)\cos n\,\theta \qquad (16)$$

where C_n is given by the formula for B_n except change A to B and F to G.

This process may be continued indefinitely, approaching the final limiting condition of the actual current density. The final current density in the two wires will be as follows:

$$i_{r\theta} = \frac{I_1}{\pi\,a^2}A_0\,J_0\,(j\,\alpha\,r) + \sum_{n=1}^{n=\infty}M_n\,J_n\,(j\,\alpha\,r)\cos n\,\theta \qquad (17)$$

and for conductor G

$$i_{u\gamma} = \frac{I_2}{\pi\,a^2}A_0\,J_0\,(j\,\alpha\,u) + \sum_{n=1}^{n=\infty}N_n\,J_n\,(j\,\alpha\,u)\cos n\,\gamma \qquad (18)$$

where $\quad M_n = A_n + B_n + C_n + \ldots \qquad (19)$

and $\quad N_n = F_n + G_n + H_n + \ldots \qquad (20)$

Thus far, only conductors A and G have been considered for simplicity. For the seven-strand problem, the effect of conductors B, C, D, E, and F may be determined by the introduction of their respective terms in the preliminary equations. The introduction of these terms will not affect the general form of the final equations for the current density as given in (17) and (18) but will affect the coefficients A_n, B_n, C_n, etc., and F_n, G_n, H_n, etc., which are dependent on the unknown currents I_1 and I_2 and on the geometry and dimensions of the circuit.

Thus, for the seven strand problem the coefficients are as follows:

$$A_0 = \frac{j\,\alpha\,a}{2\,J_1\,(j\,\alpha\,a)}\,. \qquad (21)$$

$$A_n = \frac{I_2}{\pi\,a^2}\;\frac{a^n}{s^n}\;\frac{j\,\alpha\,a}{J_{n-1}\,(j\,\alpha\,a)} + \frac{I_1}{\pi\,a^2}\;\frac{a^n}{s^n}\;\frac{j\,\alpha\,a}{J_{n-1}\,(j\,\alpha\,a)}\left[2\cos\frac{n\,\pi}{3} + \frac{2}{(\sqrt{3})^n}\cos\frac{n\,\pi}{6}+\frac{1}{(2)^n}\right]. \qquad (22)$$

$$B_n = \sum_{m=1}^{m=\infty}\frac{a^{m+n}}{s^{m+n}}\;\frac{J_{m-1}\,(j\,\alpha\,a)}{J_{n-1}\,(j\,\alpha\,a)}\left[\frac{\underline{|n+m-1}}{\underline{|n-1}\,\underline{|m}}\right]\times$$

$$\left[F_m\cos m\,\pi + 2\,A_m\cos\frac{\pi\,(m-n)}{3} + \frac{2\,A_m}{(\sqrt{3})^{m+n}}\cos\frac{\pi\,(m-n)}{6}+\frac{A_m}{(2)^{m+n}}\right]. \qquad (23)$$

C_n is given by the same expression as B_n except change A to B and F to G, likewise for any subsequent terms.

$$F_n = \frac{I_1}{\pi\,a^2}\;\frac{a^n}{s^n}\;\frac{j\,\alpha\,a}{J_{n-1}\,(j\,\alpha\,a)}\left[\cos n\,\pi + 2\cos\frac{2\,n\,\pi}{3}+2\cos\frac{n\,\pi}{3}+1\right]. \qquad (24)$$

$$G_n = \sum_{m=1}^{m=\infty}A_m\;\frac{a^{m+n}}{s^{m+n}}\;\frac{J_{m+1}\,(j\,\alpha\,a)}{J_{n-1}\,(j\,\alpha\,a)}\left[\cos n\,\pi + 2\cos\frac{2\,n\,\pi}{3}+2\cos\frac{n\,\pi}{3}+1\right]\frac{\underline{|n+m-1}}{\underline{|n-1}\,\underline{|m}}\,. \qquad (25)$$

H_n is given by the same expression as G_n except change A to B; likewise for any subsequent terms. For all terms except the sixth or multiples of the sixth, F_n, G_n, etc., will be zero.

As said before the expressions for the current density will be as given in (17) and (18) with the use of the above coefficients. The expressions for the current density in the other conductors, B, C, D, E, and F, will be similar to (17) except for the use of their respective polar coordinates.

There are now two unknown currents I_1 and I_2.

Their ratio may be determined, since the conductors of the cable are in parallel, by finding the voltage drop in each wire in terms of I_1 and I_2. Then, the voltage drops in any two parallel filaments are equal and can be equated, giving the ratio of I_1/I_2.

The simplest expression to derive is that for the drop in the central filament of the wire. This, then, is equal to the drop in any other filament. In wire A the resistance drop in the central filament is $i_0 \sigma$ where i_0 is the current density at the center. Using equation (17) this is

$$\frac{I_1}{\pi a^2} A_0 \sigma = \frac{I_1 \sigma}{\pi a^2} \frac{j \alpha a}{2 J_1 (j \alpha a)} \tag{26}$$

since $J_0(0) = 1$ and $J_n(0) = 0$ where $n \neq 0$.

The reactive drop in the central filament due to the element of current $i_{r\theta} r\, d\theta\, dr$ is

$$j \omega 2 i_{r\theta} \left(\operatorname{logh} \frac{p}{r} \right) r\, d\theta\, dr \tag{27}$$

$$= j \omega 2 \frac{I_1}{\pi a^2} \frac{j \alpha a}{2} \frac{J_0 (j \alpha r)}{J_1 (j \alpha a)} \left(\operatorname{logh} \frac{p}{r} \right) r\, d\theta\, dr$$

$$+ j \omega 2 \sum_{n=1}^{n=\infty} M_n J_n (j \alpha r) \cos n\theta \left(\operatorname{logh} \frac{p}{r} \right) r\, d\theta\, dr. \tag{28}$$

This takes into account the flux up to a certain large distance p. The expression logh denotes the hyperbolic or natural logarithm. Equation (28) was obtained by the use of equation (17). To find the reactive drop due to the entire current I_1, the above expression is integrated from $\theta = 0$ to 2π and $r = 0$ to a. The integral of the second term of (28) will be zero since $\int_0^{2\pi} \cos n\theta\, d\theta = 0$. That of the first term integrating by parts, remembering that $\alpha^2 = \frac{j \omega 4 \pi}{\sigma}$ is

$$\frac{I_1 \sigma}{\pi a^2} \frac{j \alpha a}{2} \frac{J_0 (j \alpha a)}{J_1 (j \alpha a)} + j \omega 2 I_1 \operatorname{logh} \frac{p}{a}$$

$$- \frac{I_1 \sigma}{\pi a^2} \frac{j \alpha a}{2 J_1 (j \alpha a)}. \tag{29}$$

Then the impedance drop at the center of the wire A due to I_1 is the sum of equations (26) and (29) and is

$$\frac{I_1 \sigma}{\pi a^2} A_0 J_0 (j \alpha a) + j \omega 2 I_1 \operatorname{logh} \frac{p}{a}. \tag{30}$$

The reactance drop at the same central filament in A due to currents expressed in the same form as in equations (17) and (18) in the other conductors may be added on.

Similarly, the impedance drop in the central filament of conductor G carrying current I_2 may be found. Since the two wires are in parallel, the impedance drops must be the same. The two equations may then be equated and the ratio of I_1 to I_2 determined.

For the case of the seven strand conductor the impedance drops in conductors A and G are as follows:

$$E_a = \frac{I_1 \sigma}{\pi a^2} A_0 J_0 (j \alpha a) + j \omega 2 I_2 \operatorname{logh} \frac{p}{s}$$

$$+ j \omega 2 I_1 \operatorname{logh} \frac{p^6}{6 a s^5}$$

$$+ j \omega 2 \sum_{n=1}^{n=\infty} N_n \pi a^2 \cos n\pi \frac{a^n}{n s^n} \frac{J_{n+1} (j \alpha a)}{j \alpha a}$$

$$+ j \omega 2 \pi a^2 \sum_{n=1}^{n=\infty} M_n \frac{J_{n+1} (j \alpha a)}{j \alpha a} \frac{a^n}{n s^n} \times$$

$$\left[2 \cos \frac{n\pi}{3} + \frac{2}{(\sqrt{3})^n} \cos \frac{n\pi}{6} + \frac{1}{(2)^n} \right]. \tag{31}$$

and

$$E_g = \frac{I_2 \sigma}{\pi a^2} A_0 J_0 (j \alpha a) + j \omega 2 I_2 \operatorname{logh} \frac{p}{a}$$

$$+ j \omega 12 I_1 \operatorname{logh} \frac{p}{s}$$

$$+ j \omega 12 \sum_{n=1}^{n=\infty} M_n \pi a^2 \frac{a^n}{n s^n} \frac{J_{n+1} (j \alpha a)}{j \alpha a}. \tag{32}$$

It is to be noted again that M_n and N_n are expressions involving the unknown currents I_1 and I_2 as well as the geometry of the circuit.

For the determination of the watts loss and the resistance ratio, the process is as follows:

Let $e_{r\theta} = \sigma i_{r\theta}$. (33)

Then by equation (10) of J. R. Carson's paper,[5]

$$j \mu \omega H_{r\theta} = \frac{\partial}{\partial r} e_{r\theta} \tag{34}$$

where μ is the permeability and, for this case, equal to 1. $H_{r\theta}$ is the tangential component of the magnetic force due to the currents in the wires.

Then

$$j \omega H_{r\theta} = \frac{I_1 \sigma}{\pi a^2} A_0 j \alpha J_0' (j \alpha r)$$

$$+ \sum_{n=1}^{n=\infty} \sigma M_n j \alpha J_n' (j \alpha r) \cos n\theta. \tag{35}$$

By equation (18) of Carson's paper, the true energy

5. "Wave Propagation over Parallel Wires: The Proximity Effect," by J. R. Carson, *Philosophical Mag.*, April, 1921, page 607.

transferred to or from one centimeter of wire through its surface, according to Poynting's theory, is equal to the resistance loss and is

$$\hat{I}\, I\, R' = \text{real part of } \frac{a}{4\,\pi} \int_{\theta=0}^{\theta=2\pi} \hat{e}_{a\theta}\, H_{a\theta}\, d\,\theta. \tag{36}$$

This it is noticed involves only values at the surface of the wire, so the integration is not complicated. The

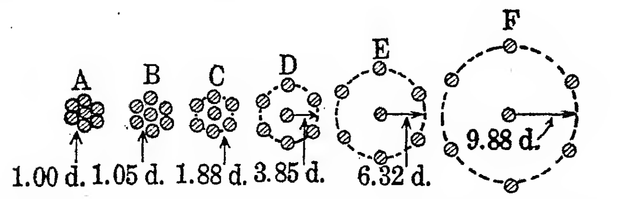

Fig. 4—Wire Spacing. (Kennelly and Affel, Reference 1)

term $\hat{e}_{a\theta}$ is the conjugate of $e_{a\theta}$, taken at the surface, and is obtained by replacing j by $-j$.

Then the loss in conductor A is

$$\frac{b}{2}\left[\hat{I}_1\, I_1\, \frac{\sigma}{\pi\, a^2}\; \frac{(u_0\, v_0' - u_0'\, v_0)}{(u_0'^2 + v_0'^2)}\right]$$

$$+ \sum_{n=1}^{n=\infty} \frac{b\,\sigma^2}{4\,\omega}\, \hat{M}_n\, M_n\, (u_n\, v_n' - u_n'\, v_n) \tag{37}$$

and the loss in conductor G is

$$\frac{b}{2}\left[\hat{I}_2\, I_2\, \frac{\sigma}{\pi\, a^2}\; \frac{(u_0\, v_0' - u_0'\, v_0)}{(u_0'^2 + v_0'^2)}\right]$$

$$+ \sum_{n=1}^{n=\infty} \frac{b\,\sigma^2}{4\,\omega}\, \hat{N}_n\, N_n\, (u_n\, v_n' - u_n'\, v_n)\,. \tag{38}$$

It is to be noticed that

$$\hat{M}_n\, M_n = |M_n|^2 \text{ and } \hat{I}_1\, I_1 = |\, I_1\,|^2, \text{ etc.}$$

The loss in any one wire at zero frequency is given

$$= \frac{I^2}{49}\; \frac{\sigma}{\pi\, a^2}\,. \tag{39}$$

Then by determination of the loss by equations (37) and (38) and the loss for the same conditions at zero frequency by (39) the ratio of losses will give the resistance ratio for conductors A and G and thence the average resistance ratio of the cable may be determined.

Results

The expressions having been derived, two calculations were made using tables of $J_n\,(b\,j\,\sqrt{j})$ as calculated by H. B. Dwight.[6] A value of $b = 2$ was chosen which for the size of wire corresponds to a frequency of 88,300 cycles/second. Calculations for two spacings, $s/a = 2$ and $s/a = 3.76$ corresponding to curves A and C of Fig. 5, were made.

The calculated results as compared with the corre-

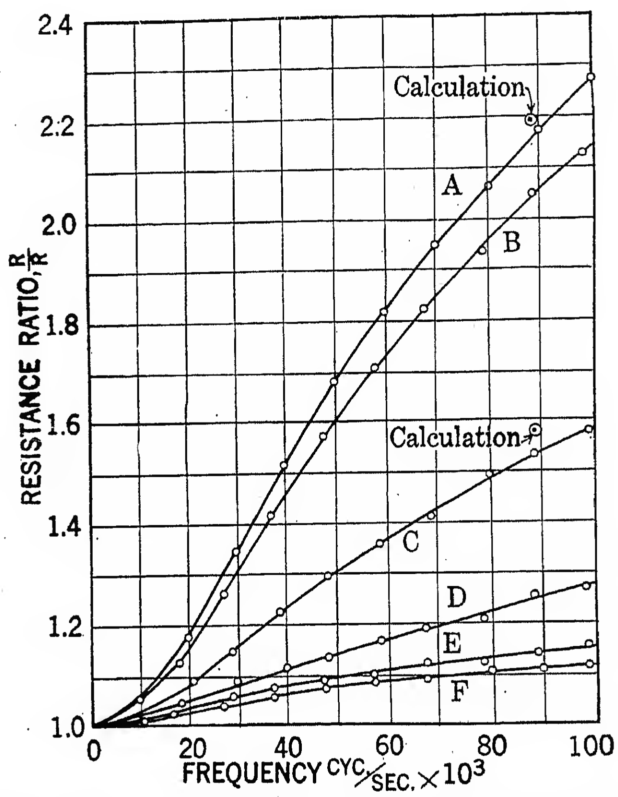

Fig. 5—Effect of Strand Spacing on the Skin Effect of a Stranded Conductor. (Kennelly and Affel, Reference 1)

sponding results of Fig. 5 for these spacings are as follows:

	$s/a = 2$	$s/a = 3.76$
Calculated...............	2.19	1.58
Figure 5 (test)............	2.15	1.53

The resistance ratio for an equivalent single round conductor for the same conditions is 2.1457.

A. I. E. E. Outstanding Features of the Past Year

President's Address

BY CUMMINGS C. CHESNEY

THE fact that the provision of the Constitution of the American Institute of Electrical Engineers which assigns the address of the President to the close rather than to the beginning of his term, seems to me to indicate a desire on the part of the Institute to have this address include in some measure, the ideas of the retiring President, acquired during his term on matters of general concern to the Institute, and to review those problems of procedure, organization and policy, which may assist the Institute to grow and develop in a way which is healthy and for the best interests of its members, for the engineering profession as a whole, for the good of the electrical industry and the communities which we represent. It seems fitting therefore at this time to bring to your attention several outstanding features of the year just past.

It has been my privilege as your President to have visited many of the more remote Sections of the Institute, for instance Salt Lake City, Los Angeles, San Francisco, Portland, Seattle, Spokane, and all of the Sections in Canada, together with many of the Sections located in the eastern cities and in the central West. I had in mind visiting all of those Sections, which, on account of their geographical location, have either never been visited by a national officer, or have been visited very infrequently. I am sure that it will be gratifying to all to learn of the increasing interest and activity in Institute affairs all over the country which it was my pleasure to find; and also to learn of the greater appreciation of the value of the Institute professionally and practically; but I have also noted many times in meeting with the officers of these Sections and discussing their problems, what an important part of our Institute activities these Sections constitute and how much of the future growth and vitalizing power of the Institute is dependent upon their success.

The Institute and its Sections can well be likened to a hydroelectric power system, where the Sections may be represented as so many small rivers reaching out in all directions, bringing their supply of power through the main artery to the central power house which converts their combined energy into a total useful effort.

At the regional meetings held by the Institute in various Sections of the country, out of a total membership of 19,000, several hundred national members may attend. For instance, at the regional meeting held at Madison, Wis., 180 were registered; at Niagara Falls 580 were registered; at New York 700; at Kansas City 225; at Bethlehem, Pa., 400. On the other hand, at the Sections meetings held during the year thousands of members get together and carry on in the many sections the real development work of the Institute. There are 95 Student Branches, which held 842 meetings last year, at which 42,650 members were registered. There are 52 of the regular Sections which held 432 meetings last year, at which 60,708 were registered; in other words there were over 100,000 members total of local Sections and Branches that attended meetings last year.

It is through the regular meetings of Sections that the young engineer makes his first contacts and receives, in many instances, the inspiration that influences the character of his life's work.

What the meetings of the Institute really mean to the members has been ably pointed out by President Scott in 1902, at the time of his presidency, when the Institute was developing at a rapid pace. A committee was formed on local Sections at this time with the authority to make arrangements for the holding of local meetings. There had been a few Sections operating at the time but active steps were then taken to develop broadly the Section idea. As Professor Scott so ably said, "In a profession, whose interests are so diversified and extended, workers should be brought together; they should have a common meeting place where discoveries may be announced, inventions discussed, engineering schemes criticized, and new undertakings presented and discussed. Here the student and professor, the investigator, the manufacturer, the operator and consulting engineer may meet upon common ground. The professor who regards lightly the work of the designing or construction engineer may find that his own cherished formulas are derived from rules and contain the constants, which the practical man has determined for himself. Association leads to mutual understanding, it curbs eccentricity and one-sided development, promoting symmetrical advancement."

During the year, I have been especially interested in watching the growth and accomplishments of all Sections of the Institute, and as might be expected, have been particularly interested in the growth and development of the Pittsfield Section, my home Section. This Section, the largest in the Institute, has a combined national and local membership of 1000 members, and it is not uncommon to have at the meetings more than 800 in attendance. This Section is not only a common meeting ground for all ambitious young engineers in the community, but at the same time it represents a definite part of the city and community life. A large number of people interested in the general meetings purchase a membership ticket and attend the popular

Presented at the Summer Convention of A. I. E. E., Detroit, Mich., June 20-24, 1927.

meetings at which important investigators, scientists, and explorers give talks and demonstrations covering their experiences. The Institute Section is the leading dignified engineering group in the community and, being interested in the community's growth, all the leading citizens feel honor-bound to belong to it. The local papers report the meetings in an elaborate way, sometimes half a page being given to a single meeting. This publicity spreads the work of the Institute beyond the city limits so that the effectiveness of the Institute as an educational and social influence is far-reaching.

In addition to the large general meetings, discussion or round-table technical meetings are held, at which the more ambitious young engineer meets on a common ground, and can engage in oral discussion, with the senior engineers of the community upon subjects of vital interest to him. Such discussion develops self-confidence, attracts attention to the younger engineer, creates the desire on his part to present papers at regional meetings, and affords an outlet for his latent energy, his enthusiasm, and his creative ability.

As he gains in experience he is placed on committees and given an opportunity to do organization work. After he has served for several years in a minor capacity, further responsibilities are added and the extent to which he continues his efforts in the interest of his Section aids his progress in securing a higher office as a reward. Simultaneously with such progress he becomes identified with the national organization, taking an active part on the main committees.

This opportunity for self-expression and growth afforded the younger engineers through the local Section is vital, for here he learns one of the fundamentals of life—that progress comes only through constant effort. The methods, which have been followed by the Pittsfield Section, develop the activities of the Section and have resulted directly in the growth and development of the individual member; they have been followed to some extent by other Sections, and while the Pittsfield idea is worth copying there are other similar successful experiences in other Sections of the Institute that are equally entitled to thorough study and consideration by the national officers.

I believe there is need for outlining a more definite policy for Section activities based on the opportunities for training and growth afforded the younger members. Such a policy would include more specific plans for lectures and round-table discussions than have heretofore been the practise, and gives a chance for development of organizing and managerial ability. It should, of course, include the opportunity to prepare papers, to engage in oral discussions, and to take a more intimate part in community work.

An engineer, because of his education, is accustomed to analyze conditions and arrive at basic truths, and if his special abilities which invite confidence could be adapted to our community problems it would have a very direct bearing on the future progress and efficiency of our industry and our country.

The Speaker Bureau idea came into effect this year, in a limited way. Through this bureau it is expected the Sections may more readily get talented speakers and lecturers. The idea is sound and should become more and more valuable each year and should be given special consideration in the future.

The Committee on Public Relations, by formulating a definite plan of procedure based, of course, on the experience of the older sections, can greatly aid in extending more rapidly the influence in their several communities of the younger or more newly organized sections.

For the purpose of the study of the section idea and the ready exchange of ideas between them, and for the purpose of extending the sections' local and national influence, our new Assistant Secretary, Mr. Henline, was added to the national executive staff last January, and while he has not authorized me to speak for him, coming from the Golden West, I know his progressive spirit makes him ever ready to render any assistance within his power to any section. May I also at this point commend the work of Prof. Harold Smith during the past several years as Chairman of the Sections Committee. The Institute is under a deep debt of gratitude to him. We cannot too much emphasize the fact that without the help of the Sections, through their vigorous and helpful growth the usefulness and future stability and the influence of the Institute will be seriously handicapped; whereas with the constructive and vitalizing work which the Sections are able to contribute to the Institute's affairs there will be every reason to expect that the past effectiveness of the Institute will continue indefinitely.

During the past year, your executive officers and your Board of Directors have given more than usual attention to the subject of Electrical Standardization. It is a subject that has had the particular attention of practically every Board of Directors since the appointment of the first Committee of Standardization by the Institute in 1898.

There has been intense interest in standardization through the older engineering organizations and also through the newer trade associations, both national and international, which has brought forth recent statements from prominent writers, such as, "Standardization is the outstanding note of this present century. It ramifies to the remotest details of our industrial regime. Its trends are highly significant. They tap all sources of scientific knowledge and affect every phase of design, production, and utilization." From another author—"Standardization is a new and outstanding influence in modern industry. It is based on an economic conception of utility, and its trends and ramifications affect every aspect of design, production, and utilization."

These are excellent and general statements of fact, but submit no reason for this recent great activity in this line, which is now so generally recognized. It is, in my opinion, largely the direct outcome of the scarcity of labor since the great war and the passage of our new immigration law, and the laudible desire to maintain and extend the high standard of living which, in this country, we have enjoyed for the past quarter of a century, and during which tens of millions of people have attained standards of comfort and of culture far higher than those of any other country in the world, and immensely in excess of anything hitherto known in the world's history.

All this argues for the maintenance and increase of the present earnings of the worker and at the same time requires the lowering of the cost of production. Standardization—which permits more readily repetitive methods of production—stimulates the invention of machines to do more rapid, more accurate, and more skilled work. It stimulates the increased use of conveyors and other mechanical means for reducing the amount of labor required for handling and transportation, all of which makes for the increase of the productivity of the individual and thus directly for the increase of the national wealth.

Standardization and mass production contribute to decreased cost, not only through the economies effected in the manufacture of the product but also in the economies effected—

1. In calculations and designs.
2. In the preparation of drawings and specifications.
3. In making propositions in response to requests from customers.
4. In selling costs.

(1) Economies are effected in design largely through savings in time of engineers by the elimination of odd types and designs, thus freeing the engineers for other work. Standardization of circuit voltage and periodicity and of permissible limits of variation of these in service, permit the manufacturer to reduce the number of varieties of machines. Furthermore, by standardized working limits, such as dielectric strength and temperature rise and other characteristics such as regulations, stalling load, starting torque, etc., the engineer can more quickly complete the engineering work on a given design by reason of his knowledge of the results which are usually obtained by working to a single standard and by the familiarity and facility he has attained through the working out of many similar designs. If he has different limits to work to in different cases obviously he must employ more variables in his calculations.

As an example consider that an engineer has been accustomed to designing a given kind of electrical machine for a high potential insulation test of a given severity and that suddenly he must design a similar machine of the same rating but for a higher insulation test. He must employ more space for insulation (granting that a better kind of insulation cannot be obtained) and this will leave him less space for iron and copper. Immediately his whole design must be changed.

(2) The standardization of material and parts and the reduction of number of varieties, leads to less and simpler drawings and specifications so that a given staff of engineers and draftsmen can deal with a much larger volume of business.

(3) By the standardization of certain requirements, the buyer and seller become accustomed to specifying machines on these bases; useless or relatively unimportant tests are less likely to be demanded by the buyer; printed specification forms may be provided which simplify the labor of making up a specification and knowledge and familiarity with similar cases (based on the same standards) enable an estimate of cost to be made more quickly and easily. These, and many other considerations which will suggest themselves to any one investigating the matter, serve to reduce the cost of the preparation of specifications and making of tenders.

(4) Standardization makes cataloging possible. The greater the degree of standardization, the greater is the simplicity and the usefulness of the catalogue. Information which can be brought to the customer through the medium of the catalogue and handbook requires less effort on the part of the sales force; or, conversely, a given sales force can deal with a larger volume of business. A salesman to be fully informed needs to carry less in his head, consequently he can handle more work in one special subject or a greater number of special subjects than would otherwise be the case.

With the less variety of sizes of a product, the less is the value of the stock which has to be carried by various distributors and products.

Thus, costs, associated with engineers, draftsmen, salesmen, and some components of overhead, are, with modern mass production, materially decreased by standardization. This is in addition to the decrease in the strictly production costs. All together these combine to increase the growth and influence of the electrical industry which is primarily our concern.

The first standards for electrical machinery generally followed by the American electrical industry were those prepared by the original Institute committee, and adopted by the Institute in June 1899. A review of the proceedings of each successive Committee of Standardization since that date indicates that all of these committees were fully aware of the flux and changes that were taking place in industry, and while these committees consisted entirely of engineers—who, by nature and training, loved law and order and who might be supposed, on that account, to be ultra-conservative and possibly timid—they were, however, endowed with the spirit of progress which collectively turned their hopes and aspirations to the future; they saw the world of industry not as a still tableau but as a moving picture

and in consequence the accomplishments of each year were progressively better than the year before.

They recognized that no standard could be final—since science was continually advancing and more effective equipment was steadily being introduced into industry—but they also recognized that changes must not be made so frequently as to unduly disturb the industry and only when a serviceable gain justified the change.

These committees to date have taken the initiative in the formulation of all electrical standards of America, and their work has been recognized as being authoritative throughout the entire world. Their procedure and their resulting standards during this period of more than a quarter of a century have been acceptable to the manufacturing and consuming interests, as well as to the general public. The industry has learned to value and to depend upon the A. I. E. E. Standards in commercial transactions covering matters of interest to all sections of the electrical industry. There has been no attempt to dictate to the industry but standards on any particular line have been introduced only when it is clear that all interested agree that the step is wise and desirable.

In the Institute Standards Committee, or in its subcommittees, the manufacturer and purchaser and the general interests came together and developed the required standards in a way which has been generally satisfactory in the past to all the interested sections of the industry. The electrical standards so issued always have been identified with the name of the Institute. It is well known that the Institute as an organization has no interest other than one of public service, which duty the Institute has always performed at its own expense. The Institute in performing this service, although voluntary, has assumed obligations during the past 28 years to the electrical industry and the public which would make it now embarrassing, if not impossible, to discontinue the present practise or lessen its responsibilities until a more simple and direct method has been devised and demonstrated.

For fear that some who have not had the opportunity to study in an intimate way the subject of Standards and Standardization, may not understand what the terms mean—I quote from my February 7th address:

"In this country and in Great Britain the term 'standardization' has grown to mean, in the minds of engineers, not only a simplification in the number of types and sizes and the securing of interchangeability, but also the laying down of performance rules or codes for all types of apparatus, including measuring instruments, prime movers, generators, transformers, and motors. Thus broadly the term 'Standard' in addition to being a measure of quality of standards of comparison, means a common unified practise, method, or dimension, which it is to the interest of industry and the community to adopt Back of any policy of standardization is primarily the purpose to furnish the public a better article or to render it a better service at a lower cost."

"In 1916 the need for a National Clearing House for engineering standards became apparent, in order to prevent duplication in standardization work and in promulgation of conflicting standards. To formulate a method of cooperation, a special joint committee—made up of representatives from the American Institute of Electrical Engineers, American Institute of Mining Engineers, American Society of Civil Engineers, American Society of Mechanical Engineers, and American Society for Testing of Materials—held its first meeting January 17, 1917. The result of this meeting and subsequent meetings was the organization of the American Engineering Standards Committee. This Committee initially consisted of representatives of these five institutions. Shortly after its organization, government representatives were admitted; and in 1919 the Constitution was broadened to permit the representation from other national bodies. The Committee now includes representatives from seven departments of the Federal Government, nine national engineering societies, and nineteen national industrial associations.

"The American Engineering Standards Committee, as at present organized, is a coordinating committee, and not a standards-making body. All standards are to be formulated and published by the respective societies, making the standard a function of great value and scope to industry. This intention is clearly expressed in the Constitution, and the American Engineering Standards Committee is primarily an administrative and policy-forming committee.

"As stated by its Secretary, perhaps the most important accomplishment of the American Engineering Standards Committee has been the actual launching of the work, setting up machinery, and securing the official cooperation of some three hundred national organizations, that is the fundamental job of breaking ground. Ninety-seven standards have been approved for the engineering and building trade—ten have to do with the electrical industry. In my opinion this is a very excellent record of accomplishments to date. The Secretary also states that everyone who has examined the work before the American Engineering Standards Committee, agrees that the whole movement of making American standards is being seriously crippled by the lack of adequate financial support. The total annual budget is $58,000. The American Institute of Electrical Engineers as such contributes to the American Engineering Standards Committee $1500 annually. Due to legal restrictions the government departments are unable to pay dues, and a special provision is made exempting them from such payments.

"The Secretary also expresses the opinion that inertia, lack of interest and understanding of the standardization method as a whole, and of its economic relations to their business on the part of executives and industrial groups, has been one of the greatest difficulties

encountered in the successful accomplishment of the committee's work. It is now proposed, by the process of amendment, to make a material and fundamental change in the Constitution of the American Engineering Standards Committee This can only be done by the unanimous consent, notwithstanding the general provision in the Constitution, providing for its amendment by a lesser vote. Such provisions only apply to incidental amendments made to carry out the purpose of the organization, and not to fundamental changes—any amendement that aims to convert the American Engineering Standards Committee into a standards-making body, or into a body that would interfere in the autonomy, in standardization work, of the representative societies would be unconstitutional.

"On February 9, 1926, during Dr. Pupin's administration, the Board of Directors authorized a brief statement of its policy to its representatives on committees, or on joint bodies, dealing with the formulation of standards;

1. To continue to develop, publish, and maintain in the name of the Institute electrical standards as it has done for the past 25 years.

2. That in doing this work the Institute will continue as it has in the past to avail itself to the fullest degree of the assistance of others—both individuals and organizations—with a view to serving the interests of all who may be properly concerned in the work.

3. That Standards, after having been developed by the Institute in accordance with 1 and 2, and adopted by the Board of Directors as Institute Standards, will be presented to the American Engineering Standards Committee for approval by it as American Standards when, in the opinion of the Institute, such a step is proper.

4. That such presentation to the American Engineering Standards Committee for their consideration for approval as American Standard will be done in full conformity with the Constitution, By-laws, and Rules of Procedure of the American Engineering Standards Committee, which Committee the Institute was instrumental in initiating and has continued to and does now endorse and support.

5. That when and if Standards of the A. I. E. E. have been further advanced to the stage of being designated as 'Approved as American Standard by the American Engineering Standards Committee,' they shall continue to be printed as standards of the A. I. E. E. with a statement of approval by the American Engineering Standards Committee added to the title page of each particular standard."

This statement I understand to mean that the American Institute of Electrical Engineers is in sympathy with the American Engineering Standards Committee as it is now organized, but that any changes affecting the fundamental character of the committee may not be acceptable to it.

Something over a year ago, a movement was undertaken to form an International Standards Association, the proposed organization to have a national committee in each country. In America, the national committee was to be the American Engineering Standards Committee. As it has been stated heretofore, its (A. E. S. C.) principal constitutional object is to supervise standardization work, but it is expressly stated in its constitution that it shall not formulate standards. There is, however, a clause in its constitution which states that one of the objects of the American Engineering Standards Committee shall be "to act as the authoritative channel of cooperation in international engineering standardization."

The Institute has subscribed to the American Engineering Standards Committee constitution. It is also a member of the United States National Committee of the International Electrotechnical Commission, which has been and is at present the body through which the electrical industry of America is conducting its international standardization work. The Institute is thus faced with a conflict of obligations. The most reasonable course is for it to go before the American Engineering Standards Committee with a frank statement of the case, and ask the American Engineering Standards Committee for its support for the course which the Institute considers to be in the best interest of the electrical industry of this country, at the present time. Under the procedure of the International Electrotechnical Commission much of value has been accomplished in establishing international electrical engineering standards. This field alone is a very large one, and it would appear unwise to abandon the present successful plan for the untried plan of an International Standards Association which does not appear to be based on such sound fundamental principles. The success of the International Electrotechnical Commission has been so considerable that it could well be duplicated in other engineering fields such as mechanical, civil, and mining fields, etc. If this were done, then we should, in addition to the International Electrotechnical Commission have an International Mechanical Commission, an International Civil Commission, etc. At some future time it might become desirable to tie these international organizations into an international technical commission, but it would at this time be premature to try to decide whether this last step would be desirable and when it should be undertaken.

It would appear that if the electrical industry is a unit in desiring to continue the International Electrotechnical Commission, and in believing that its interests would be seriously endangered by going over to a new plan, representations to this effect should be made in proper form and on the proper occasion to the American Engineering Standards Committee. While the International Electrotechnical Commission recognizes that its field is electrical, and that the desired international accomplishments in that field alone constitute an

enormous task, it is also recognized that its 20 years of experience constitute a considerable asset. The International Electrotechnical Commission has never taken advantage of this asset in a selfish way. In cases where in other fields of engineering, it should be desired to make use of the International Electrotechnical Commission's organization and experience, either temporarily or permanently, for work in other lines, the International Electrotechnical Commission is prepared, as in certain cases in the past, to offer its facilities and to adapt them to include the added work. In such cases the International Electrotechnical Commission could arrange with the organization in whose field the work belongs for additional representatives from that organization's membership. If at a later time the cooperating organization, through the establishment of its own international organization, or from any other reason for change of policy, should decide to discontinue the arrangement, this without doubt should and would meet with the hearty agreement of the International Electrotechnical Commission.

Three open problems on standardization thus confront the Institute and their importance justifies a prompt solution but not a hasty one.

First: The internal routine to be followed through its Committee on Standards for the handling of standards and standardization should be revised. This has to do primarily with the A. I. E. E. Standards.

Second: The present and future status of the American Engineering Standards Committee should be determined.

Third: The relation of the American Institute of Electrical Engineers to the United States National Committee of the International Electrotechnical Commission.

These I repeat are important and vital problems and need, for the best interest of the Institute and the industry, a prompt solution.

Report of the Board of Directors

FOR THE FISCAL YEAR ENDING APRIL 30, 1927

The Board of Directors of the American Institute of Electrical Engineers presents herewith to the membership its Forty-third Annual Report, for the fiscal year ending April 30, 1927. A general balance sheet showing the condition of the Institute's finances on April 30, 1927, together with other detailed financial statements, is included herein. The following is a brief summary of the principal activities of the Institute during the year; more detailed information has been published from month to month in the Institute JOURNAL.

Directors' Meetings.—The Board of Directors held seven meetings during the year; six in New York and one at White Sulphur Springs, W. Va. The Executive Committee acted upon various matters during intervals between Board Meetings.

Information regarding the more important activities of the Institute which have been under consideration of the Board of Directors, the committees, and the various officers, is published each month in the section of the JOURNAL devoted to "Institute Activities."

President's Visits.—President Chesney has attended the three National Conventions of the Institute held during the year and in addition visited many of the Sections. The following is a list of places visited: White Sulphur Springs, W. Va., (Summer Convention); Salt Lake City, Utah, (Pacific Coast Convention); New York, N. Y. (Winter Convention); Niagara Falls, N. Y., (Regional meeting); New York, N. Y., (Regional meeting); Los Angeles, Cal.; San Francisco, Cal.; Portland, Ore.; Seattle, Wash.; Spokane, Wash.; Vancouver, B. C.; Regina, Saskatchewan; Pittsfield, Mass.; Sharon, Pa.; Syracuse, N. Y.; Springfield, Mass.; Bridgeport, Conn.; Chicago, Ill.; Ithaca, N. Y.; Toronto, Ont.

Other meetings that President Chesney is scheduled to attend will be held in Cleveland, Ohio; Ft. Wayne, Ind.; Pittsfield, Mass. (Regional meeting); and Detroit, Mich., (Summer Convention).

Meetings.—Three national conventions of the Institute were held during the year, namely, the Summer, Pacific Coast, and Winter. The annual business meeting was held in May. Regional meetings under the auspices of the geographical districts were held in Madison, Wis., District No. 5; Niagara Falls, N. Y., District No. 1; New York, N. Y., District No. 3; Kansas City, Mo., District No. 7; Bethlehem, Pa., District No. 2. A regional meeting is also scheduled for Pittsfield, Mass., District No. 1, in May.

Annual Meeting.—The Annual Business Meeting was held at Institute headquarters, New York, on May 21, 1926. The Annual Report of the Board of Directors for the fiscal year ending April 30, 1926, was presented. The Tellers Committee made its report upon the election of officers for the administrative year beginning August 1, 1926.

Following the business meeting a talk was given on "A High-Power Laboratory for Testing Oil Circuit Breakers and other Apparatus" by W. R. Woodward of the Westinghouse Elec. & Mfg. Co. This part of the meeting was held under the auspices of the New York Section. Attendance about 600.

Summer Convention.—The Forty-second Annual Summer Convention was held at White Sulphur Springs, W. Va., June 21-25, 1926. Four technical sessions were held at which thirteen papers were presented. In addition two special sessions were devoted to the presentation of technical committee reports. The annual conference of the Sections Committee was held on Monday, June 21; forty-three Sections were represented. The entertainment program included golf and tennis tournaments, sightseeing, and special features. Attendance, about 350 members and guests.

Pacific Coast Convention.—The Fifteenth Pacific Coast Convention was held at Salt Lake City, Utah, September 6 to 9, 1926. Five technical sessions were held at which nineteen papers were presented. Attendance about 250.

Winter Convention.—The Fifteenth Winter Convention was held in New York, N. Y., February 7-11, 1927. Thirty-five technical papers were presented at eight sessions. Numerous inspection trips, a smoker, and a dinner-dance were also scheduled. Attendance was over 1900.

Regional Meetings.—During the year five Regional meetings were held. The first in District No. 5 at Madison, Wis., May 6 and 7, 1926, at which eight papers were presented during three sessions, attendance about 180; second, at Niagara Falls, N. Y. in District No. 1, May 26-28, 1926, twenty-three papers were presented at five sessions, attendance over 580; third, New York, N. Y., District No. 3, November 11 and 12, 1926, eleven papers were presented at three sessions, in addition the program also included inspection trips, a lecture, and a demonstration of the Vitaphone, registration over 700; fourth, Kansas City, Mo., District No. 7, March 17-18, 1927, twelve papers were presented at four sessions; student conference, inspection trips, attendance approximately 225; fifth, Bethlehem. Pa., District No. 2, April 21, 22,

and 23, 1927, ten papers were presented at four sessions, inspection trips, lecture, attendance about 400.

Sections.—The increased activity of the Sections mentioned last year has been well-maintained. The cooperation and affiliation of Sections with Sections of other national engineering societies and with local engineering societies have remained prominent subjects of discussion. Definite advances have been made in the development of plans to bring about closer contact between engineers and the general public. The growing interest in this subject is well illustrated by the report of the 1926 Sections Committee Conferences, and by the records of several Sections which have planned some of their meetings to attract non-engineers. The increasing number and success of the Regional Meetings (see listing under Regional Meetings) are additional evidences of Section activity. The Sections have given greater attention to cooperation with neighboring Student Branches, with very good results. Four Sections have sponsored Student Conventions, and a considerable number have held joint meetings with Branches. Several have devoted regular meetings to Student programs, and in other cases joint programs have been arranged. During the past year, a Section was organized at Louisville, Kentucky.

Student Activities.—During the past year, provisions were made for the organization in each District of a Committee on Student Activities consisting of the Vice-President, District Secretary, and the Counselors of all Branches in the District, and for the holding, under its auspices, of an annual conference on Student Activities in order that the activities of all Branches in the District might be more effectively coordinated. Such conferences have been held by the Committees of seven Districts, and have resulted in much helpful discussion of all phases of Student activities. A considerable portion of the increase in Student Branch activity may be ascribed to these conferences and to the greater efforts of the Sections and the Counselors of the Branches to establish closer relations between Sections and Branches. Very successful Student Conventions, sponsored by Sections, have been held in four Districts, with approximately twenty Branches participating and an aggregate attendance of about 800. A separate department devoted to Student activities was inaugurated in the JOURNAL in January 1927. Upon recommendations of the Committee on Student Branches, the Board of Directors approved a statement of "Suggested By-Laws for Branches," and adopted a By-Law (59A) providing for the affiliation of established student engineering societies with the Institute. New Branches were authorized during the year at Louisiana State University, University of New Hampshire, Princeton University, Municipal University of Akron, Newark College of Engineering, University of Santa Clara, Mississippi Agricultural and Mechanical College, Duke University, and Northwestern University.

SECTION AND BRANCH STATISTICS

	For Fiscal Year Ending			
	April 30 1921	April 30 1923	April 30 1925	April 30 1927
SECTIONS				
Number of Sections.	42	46	49	52
Number of Section meetings held.....	303	344	386	431
Total Attendance....	37,823	46,672	49,029	60,708
BRANCHES				
Number of Branches.	65	68	82	95
Number of Branch meetings held.....	443	503	548	842
Total Attendance....	21,629	26,893	27,603	42,650

Meetings and Papers Committee.—During the past year, the Meetings and Papers Committee has followed practically the same policy as followed during the last three years in arranging technical programs for the national conventions and regional meetings.

Three national conventions have been held and five regional meetings. At all of the conventions and meetings there was a total attendance of over 4500; 144 technical papers were presented. Detailed information on these meetings is given in the accompanying tabulation.

One of the most note-worthy developments of the year was the growth in the number of regional meetings and the increased interest taken in them. These meetings seem to be fulfilling their purpose in a very desirable manner. They allow the attendance of a large number who could not attend a national convention of the Institute. Also, they allow the presentation in a particular territory of papers on subjects which are of special interest to members in the territory.

Most of the papers presented at the regional meetings are of as high quality as those presented at national conventions. The committee, however, has followed the policy of encouraging the regional committees to include in their programs certain papers which are of particular interest locally, although they might not be selected for a national convention.

In addition to arranging for programs for the meetings held during the past fiscal year, the programs also for three future meetings have been practically fixed. For the regional meeting at Pittsfield, Massachusetts, May 25-28, 1927, and the Summer Convention in Detroit, June 20-24, 1927, the programs are complete. For the Pacific Coast Convention in Del Monte, Sept. 13-16, 1927, due very largely to the foresighted efforts of the Pacific Coast Convention committee, that program also has been rather definitely arranged.

Publication Committee.—No change in the general arrangements governing Institute publications has been made by this year's committee as the policies adopted several years ago, after many months of careful consideration, seem to have fulfilled the requirements of the membership very completely. This is attested by the fact that the JOURNAL has become generally

recognized, both at home and abroad, as the leading publication in its class.

The general scheme of publication of Institute papers is (1) publication in pamphlet form in full, these copies being available for use at the meeting where presented; (2) publication either in full or abridged, according to length, in the JOURNAL; (3) publication in full in the annual TRANSACTIONS. A few papers of merely transitory interest have been omitted from the TRANSACTIONS each year. These papers amount to less than six per cent of the total number printed and they are referred to in the TRANSACTIONS INDEX.

The TRANSACTIONS for 1926 will be completed early next Fall and will contain about 1350 pages, or 150 pages more than the previous volume. Six-hundred and eight pages have been printed to date, and 300 pages more are ready to print as soon as the current work for coming conventions permits.

Standards.—The Standards Committee has continued actively the revision of the Institute standards. There are now 23 standards available in the revised sectional or pamphlet form, several of which have themselves been revised and reprinted. The ease with which revisions can be made shows the wisdom of the change in form for the standards, adopted several years ago. Specially designed loose leaf binders can be supplied at a nominal price.

The Spanish translation of the standards has gone forward with gratifying speed. The translation of 17 of the standards has been completed and 11 have been published by the Bureau of Foreign and Domestic Commerce. By July 1 it is expected that all will be issued. The Spanish edition is printed in the same style and in the same size as the English edition. The translation has been received with interest by engineers in Spanish-speaking countries of South America. The Institute is very much indebted to the Bureau of Foreign and Domestic Commerce for the excellent manner in which the Spanish text has been published, and for the close cooperation that exists between the Bureau and the Standards Committee. American electrical manufacturers will no doubt distribute this Spanish edition widely in Spanish-speaking countries.

Six standards have been approved as American Standard by the American Engineering Standards Committee and others are before the Committee for consideration. The Institute is sole sponsor for 9 projects and joint sponsor for 9 more. These sponsorships and joint sponsorships are handled largely through the Standards Committee. Representatives on 26 additional Sectional Committees for which the Institute is not sponsor have also been appointed.

There has been during the year an increasing cooperation between the Standards Committee and the technical committees of the Institute. The chairman of each technical committee, or a member of the committee designated by the chairman as a "contact officer" is a member of the Standards Committee. Several standards have been formulated by the technical committees and accepted by the Standards Committee and in another case a subcommittee of a technical committee has been made the "working committee" of the Standards Committee on a project.

The Standards Committee has maintained close contact with the United States National Committee of the International Electrotechnical Commission, and at practically every meeting has received full reports on the work of the U. S. National Committee. This has been a very useful coordination of international problems in electrical standardization with the regular work of the committee.

U. S. National Committee of the I. E. C.—The scope of the work of the U. S. National Committee of the International Electrotechnical Commission has increased during the past year in several respects. One important increase in responsibility results from the adoption by the I. E. C. of a policy of decentralization of the secretarial work under which policy, various National Committees are asked to assume the Secretariat for one or more subjects. The U. S. N. C. has accepted the responsibility of the Secretariats on Nomenclature, on Prime Movers, and on the Rating of Rivers. This work involves stimulating and guiding the work of the International Advisory Committees on these subjects in the interim between meetings of the I. E. C.

A study of the problem of Rating of Rivers is a subject recently undertaken by the I. E. C. and illustrates the broadening scope of work of the Commission. Its importance is illustrated by the fact that the methods now used in different countries for rating the flow of rivers from the standpoint of their usefulness in the production of power, do not permit of comparative results.

Through its twelve groups of advisors the U. S. N. C. is kept closely in contact with the standardizing work of the various American organizations bearing on the subjects under consideration by the I. E. C., and has cooperated with these various organizations in the preparation of material to be presented as recommendations from America at the next meeting of the I. E. C. This meeting is to be held in September at Bellagio and Rome.

U. S. National Committee, International Commission on Illumination.—The United States Committee of the Commission is composed of representatives of various organizations interested in illumination, the Institute having three representatives on the committee. Following the plenary session in Geneva, July 1924, the general work of the committee has been proceeding. Measures are now being taken to prepare for the next session which probably will be held in the United States in 1928

Committee on Safety Codes.—The Committee on

Safety Codes investigates all matters relating to the formulation of rules for the protection of persons and property against fire, accidents, and other hazards in connection with electrical installations and equipments and to confer with similar committees of other bodies.

A subcommittee on procedure was instructed to include in its recommended procedure that the main Committee should make nominations to the President of representatives suitable for appointment on national safety code committees; that members of the A. I. E. E. now or hereafter, on safety code work, should submit drafts of their work to the Committee for review; that attention be given to having safety properly developed at the Institute meetings and in the Institute publications; that authors having papers where safety is involved be asked to emphasize that phase; that so far as possible helpful cooperation be set up with other engineering organizations.

Technical Committees.—Reports of Technical Committees embracing an outline of the year's work and a summary of progress in the industry will be presented at the Annual Convention and printed in the JOURNAL.

Membership.—During the past year the National Membership Committee has carried on the usual activities for the purpose of obtaining the desired increase in membership. This work has been conducted, as heretofore, mainly through the organization of the various Membership Committees of the Institute Sections and a report of progress of the National Committee-prepared on April 30, 1927 indicates that 1951 applications for membership have been received during the year.

The following table gives the number of new members added to the roll during the year and also the number of members whose affiliations have terminated through resignation, death, or delinquency in dues. The revised membership total as of May 1, 1927 is 18,344.

	Honorary	Fellow	Member	Associate	Total
Membership April 30, 1926.	4	625	2,623	14,906	18,158

Net increase in Membership during the year..........................186

Deaths.—The following deaths have occurred during the year.

Fellows: H. Fleetwood Albright, Adolphe A. Dion, Edward B. Ellicott, Dudley Farrand, Carl Hering, Alexander E. Keith, Edward N. Lake, Thomas D. Lockwood, James W. McCrosky, Charles E. Scribner, Ernest Thurnauer, C. Griffith Young.

Members: William Y. Avery, LeRoy Clark, Vahram Y. Davoud, Washington Devereux, George E. Luke, Leo Lustig, Shiras Morris, Russell Robb, Otto L. J. Schier, George D. Shepardson, Jesse Merrick Smith, Oberlin Smith, Charles C. Stutz, Victor H. Todd, C. Reginald Van Trump.

Associates: Charles H. Bedell, John I. Beggs, Albert P. Boeri, Alva A. Bonney, Anson W. Burchard, Paul Busher, Lawrence W. Cady, Charles A. Chapman, Edward L. Clark, Charles A. Coffin, Charles S. Cook, Richard J. Crandall, George S. Davis, Howard S. Davis, Samuel O. Edmonds, Olin J. Emmons, Louis M. Finkelstein, John J. Flather, William H. Forde, Frank E. Goodnow, Frank W. Graham, Walter Halfin, Arthur R. Henry, Albert J. Hoch, Harold O. Holte, Charles W. Holtzer, Everett D. Hunter, Charles R. Huntley, Arthur R. Jealous, Arthur Keller, Francis M. Kenny, William Korff, John V. Lannon, Don C. G. Linnell, Leo B. Masten, Charles C. Mathis, Joseph B. McCall, Henry K. McIntyre, Frederick McKeever, Walter R. McLeod, Richard N. Olds, Willis E. Osborne, George H. Pearson, Virgil Poston, John C. Potter, Lawrence W. Powers, Joseph H. Procter, William A. Rankin, Isidor M. Reguenga, Clarence E. Reid, Antonine R. Rivet, Frederick W. Roth, Earl A Schaefer, Rudolf Schmolck, Charles W. Shaifer, Frank C. Smallpiece, Leland L. Summers, Clark A. Sutton, Svatopluk Sychra, Hazen G. Tyler, Benjamin T. Viall, Edwin M. Walker, John M. Walshe, James C. Webster, Edgar M. Wilkins, Thomas W. Wilkinson, Fred W. Wilson, Ray D. Wilson.

Board of Examiners.—The Board of Examiners during the year held eleven meetings, averaging about three and one-quarter hours. It considered and referred to the Board of Directors a total of 4080 applications for admission or transfer to the higher grades.

APPLICATIONS FOR ADMISSION

Recommended for grade of Associate......	1729	
Not recommended......................	16	1745
Recommended for grade of Member.......	93	
Not recommended for admission to this grade............................	41	134
Recommended for grade of Fellow........	2	
Not recommended for admission to this grade............................	5	7
Recommended for enrolment as Students..		1834

APPLICATIONS FOR TRANSFER

Recommended for grade of Member.......	293	
Not recommended for transfer to this grade	32	325
Recommended for grade of Fellow.........	30	
Not recommended for transfer to this grade	5	35
Total number of applications considered...		4080

Scholarships.—The governing bodies of Columbia University have placed at the disposal of the Institute three scholarships in electrical engineering. In consequence, the Institute is now authorized to award a scholarship each year so that there may be one man in each class holding a scholarship on the nomination of the Institute; these scholarships will continue until further notice. Each scholarship pays $350 toward the annual tuition, and reappointment for completion of course is conditioned upon the maintenance of good standing. The award in 1926 was made to E. R. Riethmiller of the University of Michigan.

Institute Prizes.—A report of a special committee on prizes and regulations regarding them, was received and adopted by the Board, February 9, 1926. The committee suggested the yearly award of four National Prizes of $100 each and a suitable certificate, as follows: (1) Best Paper Prize, (2) First Paper Prize, (3) Best Regional Paper Prize, (4) Best Branch Paper Prize.

The following Regional Prizes may also be awarded yearly in each of the ten Geographical Districts, each prize to consist of $25 and a suitable certificate: (1) Best Paper Prize, (2) First Paper Prize, (3) Best Branch Paper Prize. For complete details and conditions of award, see the February 1927 JOURNAL.

The following National Prizes were awarded during the past year, under the conditions in force prior to the adoption of the above-mentioned regulations:

First Paper Prize for the Year 1925. To R. W. Wieseman, Schenectady, N. Y., for his paper, "A Two-Speed Salient-Pole Synchronous Motor."

Transmission Prize for the Year 1925. To J. H. Cox and J. W. Legg, East Pittsburgh, Pa., for their paper, "The Klydonograph and its Application to Surge Investigation."

Various Regional Prizes have been awarded as announced from time to time in the issues of the monthly JOURNAL.

The National awards for papers presented during the year 1926 have been made and the prizes will be presented at the annual Summer Convention, in Detroit, in June, as follows:

Best Paper Prize for the Year 1926. To F. M. Farmer, New York, for his paper, "Tests of Paper-Insulated High-Tension Cable."

First Paper Prize for the Year 1926. To Othmar K. Marti, Camden, N. J., for his paper, "Steel Enclosed Power Rectifiers."

Best Regional Paper Prize for the Year 1926. To F. M. Farmer, New York, for his paper, "Tests of Paper-Insulated High-Tension Cable."

Best Branch Paper Prize for the Year 1926. To R. A. Schaefer, of Marquette University Branch, for his paper, "A Study of Transverse Armature Reaction in Synchronous Machines by Means of a Second Machine with an Adjustable Stator."

Edison Medal.—The Edison Medal awarded last year to Dr. Harris J. Ryan, Stanford University, California, "for his contributions to the science and the art of high-tension transmission of power," was presented to Dr. Ryan at the Pacific Coast Convention, Salt Lake City, Utah, on September 8, 1926.

John Fritz Medal.—The John Fritz Medal Board of Award, which is composed of representatives of the national societies of Civil, Mining, Mechanical, and Electrical Engineers, awarded the 23rd medal to Elmer Ambrose Sperry of New York, "for the development of the gyro-compass and the application of the gyroscope to the stabilization of ships and aeroplanes." The medal was presented at New York, at the annual meeting of the American Society of Mechanical Engineers, December 7, 1926.

Lamme Gold Medal.—A bequest was made by the late B. G. Lamme, to cover the cost of an annual award by the Institute of a gold medal, to a member who has shown meritorious achievement in the development of electrical apparatus. The conditions governing the award of the Lamme Gold Medal are now being prepared by the Committee on Award of Institute Prizes.

Commission of Washington Award.—The Washington Award for 1926 was voted to John Watson Alvord, Consulting Engineer, Chicago, Ill.

The award is made annually "to an engineer whose work in some special instance, or whose services in general have been noteworthy for their merit in promoting the public good," by a committee composed of nine representatives of the Western Society of Engineers and two each from the A. S. C. E., the A. I. M. E., the A. S. M. E., and the A. I. E. E.

Employment Service.—The employment service which the Institute has maintained for many years is now conducted as a cooperative bureau in conjunction with a similar service maintained by the National Societies of Civil, Mining, and Mechanical engineers under the title, "Engineering Societies Employment Service." In addition to the main office in the Engineering Societies Building, New York, offices have been opened in Chicago in cooperation with the Western Society of Engineers and in San Francisco under similar arrangements with the California Section, American Chemical Society, and Engineers Club of San Francisco. Arrangements have been completed to open a branch office in Denver, Colorado in cooperation with the Colorado Engineering Society. It is hoped to continue this development from year to year as conditions warrant. The service is supported by the joint contributions of the societies and their individual members who are benefited. As in the past it consists principally in acting as a medium for bringing together the employer and the employee. In addition to the publication of the "Employment Service Bulletin" in the monthly JOURNALS, weekly subscription bulletins are issued for employers and those seeking positions.

American Engineering Council.—This organization is the instrument of the constituent engineering societies through which the engineering profession may

contribute toward the solution of the social, economic, and political problems of the day.

The annual meeting of the American Engineering Council was held in Washington, D. C., in January 1927. Meetings of the Administrative Board have been held during the year. The activities of Council have covered an extensive field, the following being a partial summary: study of accidents and production; forest conservation; represented on National Board for Jurisdictional Awards; has endorsed the development of the Patent office and endeavored to secure a new building; Public Works Bill written to conform with recommendations of Councils' committee; report of Committee on Radio Broadcasting presented to Federal Radio Commission; preliminary study of stream pollution; has Committee on Street Signs, Signals, and Markings with local committees in over one hundred cities; etc.

United Engineering Society.—This Society performs for the national societies of Civil, Mining, Mechancial, and Electrical Engineers, certain specific acts which are governed by contracts; the primary function of the United Society being to hold in trust and to administer for these societies the Engineering Societies Building, in which the headquarters of the national societies are located.

Extracts from the annual financial report of the United Engineering Society were published in the March 1927 JOURNAL.

Engineering Societies Library.—The library of the Institute is combined with the libraries of the national societies of Civil, Mining, and Mechancial Engineers, administered as the "Engineering Societies Library" under the direction of the Library Board of the United Engineering Society; this board is composed of representatives of each of the four societies referred to above.

In order to place the facilities of the library at the disposal of persons residing at a distance from New York, a Library Service Bureau has been established, and a staff of expert searchers and translators is employed to cover almost any engineering topic, in the following manner: abstracting, translating, bibliographing, statistical searches and reports, searches for patent purposes, copying, preparing reference cards, etc. A lending department is also maintained.

A copy of the annual report of the Engineering Societies Library covering the calender year 1926, may be obtained by applying to Institute headquarters.

Engineering Foundation.—Engineering Foundation is a trust fund established in 1914 by Ambrose Swasey, of Cleveland, Ohio, by gifts to United Engineering Society as a nucleus of a large endowment "for the furtherance of research in science and in engineering, or for the advancement in any other manner of the profession of engineering and the good of mankind." The fund has been generously increased through the gifts of Edward D. Adams and others, and also through bequest under the will of the late Henry R. Towne. It is administered by the Engineering Foundation Board upon which the Institute and other national engineering societies are represented. The Board is a Department of United Engineering Society.

The Foundation has made appropriations for various research projects and has cooperated in others.

The annual report of the Foundation is available in printed form.

Representatives.—The Institute has continued its representation upon various national committees and other local and national bodies with which it has been affiliated in past years, and has accepted sponsorship and appointed representatives upon a number of new Sectional Committees of American Engineering Standards Committee. A complete list of representatives is published frequently in the JOURNAL.

Finance Committee.—During the year the committee has held monthly meetings, has passed upon the expenditures of the Institute for various purposes, and otherwise performed the duties prescribed for it in the Constitution and By-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report follows:

Respectfully submitted for the Board of Directors.

F. L. HUTCHINSON,

National Secretary.

NEW YORK

May 16, 1927.

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

We have made a general audit of your accounts for the year ended April 30, 1927, and submit the following exhibits and schedule:

Exhibit

A—Balance Sheet, April 30, 1927.

Schedule

1—Reserve Capital Fund—Securities.

B—Summary of Income and Profit and Loss for the Year Ended April 30, 1927.

WE HEREBY CERTIFY that in our opinion Exhibits A and B correctly set forth the financial condition of the Institute at April 30, 1927, and the results of its operations for the year ended that date.

Yours truly,
HASKINS & SELLS

Exhibit A.

Balance Sheet, April 30, 1927

ASSETS

Real Estate:			
One-fourth interest in United Engineering Society's Land, Building, and Building Equipment, 25 to 33 West 39th Street (Depreciation carried on books of United Engineering Society)			$493,352.60
Equipment:			
Library—Volumes and Fixtures		$40,607.84	
Works of Art, Paintings, etc.		3,001.35	
Office Furniture and Fixtures	$20,917.93		
Less Reserve for Depreciation (including $5,556.81 funded)	10,445.97	10,471.96	
Total Equipment			54,081.15
Working Assets:			
"Transactions" etc.		$ 3,821.50

ADVISORY COMMITTEE TO THE MUSEUMS OF THE PEACEFUL ARTS

J. P. Jackson, Chairman, 130 E. 15th St., New York, N. Y.

Randolph H. Nexsen, George K. Thompson.

TECHNICAL COMMITTEES

COMMUNICATION

H. P. Charlesworth, Chairman, 195 Broadway, New York, N. Y.

F. L. Baer, D. H. Gage, F. A. Raymond,
L. W. Chubb, S. P. Grace, Chester W. Rice,
J. L. Clarke, P. J. Howe, J. K. Roosevelt,
Charles E. Davies, F. H. Kroger, H. A. Shepard,
H. W. Drake, Ray H. Manson, J. F. Skirrow,
Major P. W. Evans, R. D. Parker, E. B. Tuttle,
R. D. Evans, H. S. Phelps, K. L. Wilkinson,
E. H. Everit, Lt.Commdr. B.B.Ralston, F. A. Wolff,
L. F. Fuller, C. A. Wright.

EDUCATION

P. M. Lincoln, Chairman, Franklin Hall, Cornell University, Ithaca, N. Y.
R. E. Doherty, Vice-Chairman, Schenectady, N. Y.

C. A. Adams, J. P. Jackson, Harold B. Smith,
Edward Bennett, John Mills, R. W. Sorensen,
Nelson J. Darling, H. H. Norris, J. B. Whitehead,
W. C. Eglin, Harold Pender, W. R. Whitney,
W. L. Robb, W. E. Wickenden.

ELECTRICAL MACHINERY

H. M. Hobart, Chairman, General Electric Co., Schenectady, N. Y.
J. C. Parker, Vice-Chairman, Brooklyn, N. Y.
E. B. Pacton, Secretary, General Electric Co., Schenectady, N. Y.

C. A. Adams, G. H. Garcelon, O. K. Marti,
P. L. Alger, C. M. Gilt, V. M. Montsinger,
B. F. Bailey, Harold Goodwin, C. A. Mudge,
B. L. Barns, J. L. Hamilton, F. D. Newbury,
B. A. Behrend, W. E. Haseltine, L. C. Nichols,
C. O. Bergstrom, R. A. Hentz, N. L. Pollard,
A. C. Bunker, C. F. Hirshfeld, C. H. Sanderson,
James Burke, B. G. Jamieson, R. F. Schuchardt,
W. M. Dann, J. A. Johnson, A. Still,
L. L. Elden, V. Karapetoff, E. C. Stone,
G. Faccioli, A. H. Kehoe, R. H. Tapscott,
C. J. Fechheimer, P. M. Lincoln, R. B. Williamson,
W. J. Foster, A. M. MacCutcheon, H. L. Zabriskie.

ELECTRIC WELDING

J. C. Lincoln, Chairman, Coit Road and Kirby Avenue, Cleveland, Ohio

C. A. Adams, Alexander Churchward, Ernest Lunn,
P. P. Alexander, O. H. Eschholz, J. W. Owens,
C. W. Bates, F. M. Farmer, William Spraragen,
Ernest Bauer, H. M. Hobart, H. W. Tobey,
A. M. Candy, C. J. Holslag, Ernest Wanamaker.
C. L. Ipsen,

ELECTROCHEMISTRY AND ELECTROMETALLURGY

G. W. Vinal, Chairman, Bureau of Standards, Washington, D. C.

Lawrence Addicks, Safford K. Colby, Magnus Unger,
A. N. Anderson, F. A. J. Fitzgerald, J. B. Whitehead,
T. C. Atchison, Walter E. Holland, J. L. Woodbridge,
Farley G. Clark, F. A. Lidbury, J. L. McK. Yardley.
C. G. Schluederberg,

ELECTROPHYSICS

V. Karapetoff, Chairman, Cornell University, Ithaca, N. Y.
Carl Kinsley, Secretary, 22 Lynwood Road, Scarsdale, N. Y.

Oliver E. Buckley, W. B. Kouwenhoven, Chester W. Rice,
V. Bush, K. B. McEachron, J. Slepian,
J. F. H. Douglas, R. A. Millikan, Harold B. Smith,
Charles Fortescue, J. H. Morecroft, Irving B. Smith,
Carl Kinsley, J. B. Whitehead.

INSTRUMENTS AND MEASUREMENTS

A. E. Knowlton, Chairman, Dunham Laboratory, Yale University, New Haven, Conn.
E. D. Doyle, Vice-Chairman, New York, N. Y.

O. J. Bliss, C. F. Hanson, L. T. Robinson,
Perry A. Borden, W. B. Kouwenhoven, E. J. Rutan,
W. M. Bradshaw, P. M. Lincoln, B. W. St. Clair,
H. B. Brooks, W. M. McConahey, G. A. Sawin,
J. R. Craighead, Wm. J. Mowbray, I. B. Smith,
Melville Eastham, H. A. Perkins, H. M. Turner,
W. M. Goodwin, Jr., R. T. Pierce, Roy Wilkins.

APPLICATIONS TO IRON AND STEEL PRODUCTION

A. G. Pierce, Chairman, 1329 Guardian Building, Cleveland, Ohio

A. C. Bunker, S. L. Henderson, J. W. Speer,
A. C. Cummins, R. H. Keil, G. E. Stoltz,
F. B. Crosby, W. C. Kennedy, T. S. Towle,
J. H. Hall, A. G. Place, J. D. Wright.
F. O. Schnure,

PRODUCTION AND APPLICATION OF LIGHT

P. S. Millar, Chairman, Electrical Testing Laboratories, 80th St. & East End Ave., New York

W. T. Blackwell, G. C. Hall, F. H. Murphy,
J. M. Bryant, L. A. Hawkins, F. A. Rogers,
J. R. Cravath, H. H. Higbie, B. E. Shackelford,
W. T. Dempsey, C. L. Kinsloe, C. J. Stahl,
William Esty, A. S. McAllister, G. H. Stickney.
George S. Merrill,

APPLICATIONS TO MARINE WORK

G. A. Pierce, Chairman, Wm. Cramp & Sons S. & E. B. Co., Philadelphia, Pa.
R. A. Beekman, Vice-Chairman, Schenectady, N. Y.

Commdr. C. S. Gillette, A. Kennedy, Jr., R. L. Witham,
E. M. Glasgow, Commdr. M. A. Libbey, H. M. Southgate,
H. F. Harvey, Jr., J. B. Lunsford, W. E. Thau,
Wm. Hetherington, Jr., E. B. Merriam, C. P. Turner,
H. L. Hibbard, I. H. Osborne, A. E. Waller,
J. S. Jones, William H. Reed, J. L. Wilson.

APPLICATIONS TO MINING WORK

W. H. Lesser, Chairman, Madeira Hill & Co., Frackville, Pa.

M. C. Benedict, Carl Lee, W. F. Schwedes,
F. N. Bosson, John A. Malady, E. D. Stewart,
Graham Bright, Charles H. Matthews, F. L. Stone,
L. C. Ilsley, F. C. Nicholson, W. A. Thomas,
G. M. Kennedy, H. F. Pigg, E. B. Wagner,
R. L. Kingsland, L. L. Quigley, J. F. Wiggert,
A. B. Kiser, Herbert S. Sands, C. D. Woodward.

GENERAL POWER APPLICATIONS

A. M. MacCutcheon, Chairman, 1088 Ivanhoe Road, Cleveland, Ohio
E. W. Henderson, Secretary, 1088 Ivanhoe Road, Cleveland, O.

A. E. Arnold, H. D. James, H. W. Price,
D. H. Braymer, P. C. Jones, H. L. Smith,
R. C. Deale, A. C. Lanier, A. H. Stebbins,
C. W. Drake, W. S. Maddocks, E. C. Stone,
J. F. Gaskill, N. L. Mortensen, W. H. Timbie,
Clyde D. Gray, K. A. Pauly, F. M. Weller,
C. Francis Harding, D. M. Petty, W. C. Yates.

POWER GENERATION

W. S. Gorsuch, Chairman, 600 W. 59th St., New York, N. Y.
J. T. Lawson, Vice-Chairman, Newark, N. J.

Vern E. Alden, H. A. Kidder, M. M. Samuels,
H. A. Barre, W. H. Lawrence, F. A. Scheffler,
E. T. Brandon, F. T. Leilich, R. F. Schuchardt,
N. E. Funk, James Lyman, Arthur R. Smith,
W. S. Gorsuch, W. E. Mitchell, Nicholas Stahl,
C. F. Hirshfeld, I. E. Moultrop, B. Tikhonovitch,
Francis Hodgkinson, W. M. White.

POWER TRANSMISSION AND DISTRIBUTION

Philip Torchio, Chairman, 124 E. 15th St., New York, N. Y.
P. H. Chase, Vice-Chairman, Philadelphia, Pa.
R. N. Conwell, Vice-Chairman, Newark, N. J.
R. H. Tapscott, Vice-Chairman, New York, N. Y.

R. W. Atkinson, L. L. Elden, C. R. Oliver,
A. O. Austin, R. D. Evans, F. W. Peek, Jr.,
F. G. Baum, F. M. Farmer, D. W. Roper,
R. D. Booth, C. L. Fortescue, C. E. Schwenger,
J. A. Brundige, C. D. Gray, A. E. Silver,
V. Bush, K. A. Hawley, M. L. Sindeband,
George F. Chellis, J. P. Jollyman, H. C. Sutton,
Wallace S. Clark, A. H. Kehoe, Percy H. Thomas,
Edith Clarke, C. H. Kraft, W. K. Vanderpoel,
John C. Damon, A. H. Lawton, Theodore Varney,
W. A. Del Mar, E. A. Loew, H. S. Warren,
Herbert H. Dewey, W. E. Meyer, R. J. C. Wood,
W. E. Mitchell,

PROTECTIVE DEVICES

F. L. Hunt, Chairman, Turners Falls Power & Electric Co., Greenfield, Mass.
H. R. Summerhayes, Vice-Chairman, Schenectady, N. Y.
E. A. Hester, Secretary, 435 Sixth Ave., Pittsburgh, Pa.

Raymond Bailey, W. S. Edsall, H. Halperin, F. C. Hanker, J. Allen Johnson, M. G. Lloyd, H. C. Louis, W. B. Kirke, K. B. McEachron, W. H. Millan, L. J. Moore, J. M. Oliver, E. J. Rutan, H. P. Sleeper, E. C. Stone, A. H. Sweetnam, A. Royal Wood.

RESEARCH

John B. Whitehead, Chairman, Johns Hopkins University, Baltimore, Md.
F. W. Peek, Jr., Vice-Chairman, Pittsfield, Mass.

Edward Bennett, V. Bush, E. H. Colpitts, E. E. F. Creighton, W. F. Davidson, W. A. Del Mar, B. Gherardi, V. Karapetoff, A. E. Kennelly, M. G. Lloyd, C. E. Magnusson, Harold Pender, E. W. Rice, Jr., D. W. Roper, Clayton H. Sharp, C. E. Skinner, Harold B. Smith, R. W. Sorensen.

TRANSPORTATION

J. V. B. Duer, Chairman, Pennsylvania Railroad, Altoona, Pa.

E. R. Hill, W. K. Howe, D. C. Jackson, H. A. Kidder, John Murphy, W. S. Murray, W. B. Potter, N. W. Storer, W. M. Vandersluis, Richard H. Wheeler.

A. I. E. E. Representatives

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE COUNCIL

M. I. Pupin, John B. Taylor.

AMERICAN BUREAU OF WELDING

H. M. Hobart.

AMERICAN COMMITTEE ON ELECTROLYSIS

B. J. Arnold, N. A. Carle, F. N. Waterman.

AMERICAN ENGINEERING COUNCIL ASSEMBLY

H. H. Barnes, Jr., A. W. Berresford, *C. C. Chesney, H. W. Eales, *John H. Finney, *M. M. Fowler, H. M. Hobart, F. L. Hutchinson, William McClellan, L. F. Morehouse, I. E. Moultrop, *Farley Osgood, A. G. Pierce, M. I. Pupin, E. W. Rice, Jr., *Charles F. Scott, *C. E. Skinner, Calvert Townley.

*Members of Administrative Board

AMERICAN ENGINEERING STANDARDS COMMITTEE

H. M. Hobart, J. F. Meyer, C. E. Skinner,
H. S. Osborne, John C. Parker, L. T. Robinson, Alternates.

AMERICAN MARINE STANDARDS COMMITTEE

R. A. Beekman.

AMERICAN YEAR BOOK, ADVISORY BOARD

Edward Caldwell.

APPARATUS MAKERS AND USERS, COMMITTEE OF NATIONAL RESEARCH COUNCIL

C. E. Skinner.

BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY

Bancroft Gherardi, G. L. Knight, Calvert Townley.

CHARLES A. COFFIN FELLOWSHIP AND RESEARCH FUND COMMITTEE

C. C. Chesney.

ELIMINATION OF FATIGUE, COMMITTEE ON, SOCIETY OF INDUSTRIAL ENGINEERS

C. Francis Harding.

ENGINEERING FOUNDATION BOARD

Gano Dunn, L. B. Stillwell.

JOHN FRITZ MEDAL BOARD OF AWARD

C. C. Chesney, Gano Dunn, M. I. Pupin, Farley Osgood.

JOINT COMMITTEE ON WELDED RAIL JOINTS

D. D. Ewing, A. P. Way.

JOINT CONFERENCE COMMITTEE OF FOUNDER SOCIETIES

The Presidents and Secretaries, *ex officio*.

LIBRARY BOARD OF UNITED ENGINEERING SOCIETY

Edward D. Adams, E. B. Craft, F. L. Hutchinson, W. B. Jackson, W. I. Slichter.

NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE

J. P. Jackson.

NATIONAL FIRE WASTE COUNCIL

John H. Finney, J. P. Jackson.

NATIONAL MUSEUM OF ENGINEERING AND INDUSTRY BOARD OF TRUSTEES

Gano Dunn.

NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION

John B. Whitehead, Cary T. Hutchinson, E. W. Rice, Jr.,
F. L. Hutchinson, *ex officio*.

NATIONAL SAFETY COUNCIL, ELECTRICAL COMMITTEE OF A. S. S. E. ENGINEERING SECTION

J. P. Jackson.

THE NEWCOMEN SOCIETY

E. B. Craft.

RADIO ADVISORY COMMITTEE, BUREAU OF STANDARDS

A. E. Kennelly.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION BOARD OF INVESTIGATION AND COORDINATION

Gano Dunn, Frank B. Jewett.

U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION

A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp.

WASHINGTON AWARD, COMMISSION OF

L. A. Ferguson, Charles F. Scott.

U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION

C. A. Adams, C. C. Chesney, *ex officio*, L. W. Chubb, W. A. Del Mar, Gano Dunn, B. Gherardi, H. M. Hobart, D. C. Jackson, F. B. Jewett, A. E. Kennelly, H. A. Kidder, *ex officio*, John W. Lieb, F. V. Magalhaes, C. O. Mailloux, A. S. McAllister, William McClellan, J. F. Meyer, *ex officio*, F. D. Newbury, H. S. Osborne, Farley Osgood, F. W. Peek, E. W. Rice, Jr., L. T. Robinson, D. W. Roper, Charles F. Scott, C. H. Sharp, C. E. Skinner, N. W. Storer, John B. Taylor, Elihu Thomson, R. B. Williamson.

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	A. R. Holden	H. L. Steinbach
Atlanta	C. E. Bennett	W. F. Oliver
Baltimore	W.B.Kouwenhoven	R. T. Greer
Boston	Hartley Rowe	W. H. Colburn
Chicago	K. A. Auty	William Wurth
Cincinnati	W. P. Beattie	L. J. Gregory
Cleveland	H. L. Grant	W. E. McFarland
Columbus	A. W. Janowitz	E. A. Williams
Connecticut	A. E. Knowlton	R. G. Warner
Denver	W. H. Edmunds	R. B. Bonney
Detroit-Ann Arbor	Harold Cole	F. H. Riddle
Erie	F. A. Tennant	L. H. Curtis
Fort Wayne	D. W. Merchant	C. F. Beyer
Indianapolis-Lafayette	J. B. Bailey	C. A. Fay
Ithaca	R. F. Chamberlain	G. F. Bason
Kansas City	R. L. Baldwin	S. M. De Camp
Lehigh Valley	W. E. Lloyd, Jr.	G. W. Brooks
Los Angeles	R. E. Cunningham	L. C. Williams
Louisville	D. C. Jackson, Jr.	W. C. White
Lynn	D. F. Smalley	Chas. Skoglund
Madison	E. J. Kallevang	H. J. Hunt
Mexico	Carlos Macias	G. Solis Payan
Milwaukee	H.L.VanValkenberg	R. G. Lockett
Minnesota	S. B. Hood	M. E. Todd
Nebraska	C. W. Minard	N. W. Kingsley
New York	E. B. Meyer	O. B. Blackwell
Niagara Frontier	H. B. Alverson	A. W. Underhill, Jr.
Oklahoma	E. R. Page	C. C. Stewart
Panama	L. W. Parsons	I. F. McIlhenny
Philadelphia	Louis J. Costa	R. H. Silbert
Pittsburgh	D. M. Simons	W. C. Goodwin
Pittsfield	E. F. Gehrkens	C. H. Kline
Portland, Ore	J. C. Henkle	J. E. Yates
Providence	Edwin E. Nelson	F. W. Smith
Rochester	Earl C. Karker	Wade H. Reichard
St. Louis	L. F. Woolston	L. P. Van Houten
San Francisco	D. I. Cone	A. G. Jones
Saskatchewan	S. R. Parker	W. P. Brattle
Schenectady	R. E. Doherty	R. F. Franklin
Seattle	C. E. Mong	C. R. Wallis
Sharon	H. L. Cole	L. H. Hill
Southern Virginia	W. S. Rodman	J. H. Berry
Spokane	Richard McKay	James B. Fisken
Springfield, Mass	L. F. Curtis	J. Frank Murray
Syracuse	C. E. Dorr	F. E. Verdin
Toledo	O. F. Rabbe	Max Neuber
Toronto	M. B. Hastings	F. F. Ambuhl
Urbana	J. T. Tykociner	L. B. Archer
Utah	B. C. J. Wheatlake	D. L. Brundige
Vancouver	R. L. Hall	C. W. Colvin
Washington, D. C.	C. A. Robinson	L. E. Reed
Worcester	C. F. Hood	F. C. Crosby

Total 52

LIST OF BRANCHES

Name and Location	Chairman	(Secretary)
Akron, Municipal University of, Akron, Ohio.	Lee J. Shaffer	S. K. Worthen
Alabama Poly. Inst., Auburn, Ala.	T. S. Lynch	P. E. Sandlin
Alabama, Univ. of, University, Ala.	Sewell St. John	J. M. Cardwell, Jr.
Arizona, Univ. of, Tucson, Ariz.	J. W. Cruse	Audley Sharpe
Arkansas, Univ. of, Fayetteville, Ark.	Carroll Walsh	W. H. Mann, Jr.
Armour Inst. of Tech., Chicago, Ill.	M. T. Goetz	C. W. Schramm
Brooklyn Poly. Inst., Brooklyn, N. Y.	William Berger	Joseph Heller
Bucknell Univ., Lewisburg, Pa.	A. Fogelsanger	J. D. Johnson
California Inst. of Tech., Pasadena, Calif.	Thomas L. Gottier	Allan E. Capon
California, Univ. of, Berkeley, Calif.	F. H. McCune	A. G. Montin
Carnegie Inst.of Tech., Pittsburgh, Pa.	J. R. Power	R. O. Perrine
Case School of Applied Science, Cleveland, O.	G. J. Currie	R. C. Taylor
Catholic Univ. of America, Washington, D. C.	W. S. Sparks	C. S. Daily, Jr.
Cincinnati, Univ. of, Cincinnati, O.	C. W. Taylor	W. C. Osterbrock
Clarkson Coll. of Tech., Potsdam, N.Y.	H. J. Myrback	W. E. Turnbull
Clemson Agri. College, Clemson College, S. C.	L. R. Miller	J. U. Wilson
Colorado State Agri. College, Ft. Collins, Colo.	Harold Newsome	Harold Groat
Colorado, Univ. of, Boulder, Colo.	A. D. Thomas	J. A. Setter
Cooper Union, New York, N. Y.	H. T. Wilhelm	E. T. Reynolds
Denver, Univ. of, Denver, Colo.	Harold Henson	Alex. A. Ohlson
Drexel Institute, Philadelphia, Pa.	H. D. Baker	R. S. Bininger, Jr.
Duke University, Durham, N. C.	Oren Long	W. C. Earnhardt

LIST OF BRANCHES—*Continued*

Name and Location	Chairman	(Secretary)
Florida, Univ. of, Gainesville, Fla.	W. Stanwix-Hay	R. D. Ross
Georgia School of Tech., Atlanta, Ga.	W. M. McGraw	F. L. Kaestle
Idaho, Univ. of, Moscow, Idaho	J. W. Gartin	S. Blore
Iowa State College, Ames, Iowa	A. G. Baumgartner	J. B. Cecil
Iowa, State Univ. of, Iowa City, Iowa	Theo. VanLaw	E. J. Hartman
Kansas State Coll., Manhattan, Kans.	A. M. Young	John Yost
Kansas, Univ. of, Lawrence, Kans.	Elmer Bayles	Miss Lottye Young
Kentucky, Univ. of, Lexington, Ky.	R. W. Spicer	C. D. McClanahan
Lafayette College, Easton, Pa.	Herbert Heinrich	Daniel Paul
Lehigh University, Bethlehem, Pa.	A. W. Staller	J. Lloyd Dancy
Lewis Institute, Chicago, Ill.	James S. Howe	O. D. Westerberg
Louisiana State University, Baton Rouge, La.	K. J. Ozment	E. P. Athens
Maine, University of, Orono, Me.	P. E. Watson	R. F. Scott
Marquette Univ., Milwaukee, Wis.	R. M. Franey	E. T. Baldwin
Massachusetts Inst. of Tech., Cambridge, Mass.	Constantine Bary	E. A. Michelman
Michigan State Coll., East Lansing	W. H. Bartels	J. C. Phelps
Michigan, Univ. of, Ann Arbor, Mich.	M. H. Nelson	H. R. Stevenson
Milwaukee, Engg. School of, Milwaukee, Wis.	Joseph Havlick	W. H. Freisleben
Minnesota, Univ. of, Minneapolis, Minn.	C. H. Burmeister	J. H. DuBois
Mississippi Agri. & Mech. Coll., A. & M. College, Miss.	H. M. Alford	B. W. Robins
Missouri School of Mines and Metallurgy, Rolla, Mo.	H. H. Brittingham	E. J. Gregory
Missouri, Univ. of, Columbia, Mo.	V. L. Tiller	J. L. Egbert
Montana State Coll., Bozeman, Mont.	W. E. Pakala	J. A. Thaler
Nebraska, Univ. of, Lincoln, Neb.	H. H. Brown	R. D. Reed
Nevada, Univ. of, Reno, Nev.	Kenneth Knopf	Clark Amens
Newark Coll. of Engg., Newark, N. J.	H. G. Patton	C. H. Clarendon, Jr.
New Hampshire, Univ. of, Durham, N. H.	T. C. Tappan	F. W. Hussey
New York, Coll. of the City of, New York, N. Y.	Harold Wolf	A. H. Rapport
New York Univ., New York, N. Y.	H. U. Hefty	Henry Och
North Carolina State College, Raleigh, N. C.	J. W. Fagan	W. E. Mathews
North Carolina, Univ. of, Chapel Hill	H.E.Thompson, Jr.	W. N. Michal
North Dakota, Univ. of, Grand Forks, N. D.	Alfred Botten	Nels Anderson
Northeastern Univ., Boston, Mass.	W. P. Raffone	John L. Clark
Notre Dame, Univ.of, Notre Dame, Ind.	W. C. Davis	C. H. Schamel
Ohio Northern Univ., Ada, Ohio	M. W. Heft	P. W. Wadsworth
Ohio State Univ., Columbus, O.	A. B. Crawford	L. G. Stewart
Ohio University, Athens, Ohio	Clarence Kelch	Glen R. Smith
Oklahoma A. & M. Coll., Stillwater, Okla.	B. Fonts	J. Robertson
Oklahoma, Univ. of, Norman, Okla.	G. B. Brady	H. C. Mitschrich
Oregon Agri. College, Corvallis, Ore.	F. D. Crowther	E. F. Reddy
Pennsylvania State College, State College, Pa.	F. F. Wilkins	C. C. Huggler
Pennsylvania, Univ. of, Philadelphia	F. H. Riordan, Jr.	W. H. Hamilton
Pittsburgh, Univ. of, Pittsburgh, Pa.	M. G. Jarrett	D. P. Mitchell
Princeton Univ., Princeton, N. J.	John Reine	J. M. Myers
Purdue Univ., Lafayette, Ind.	H. L. Lindstrom	H. A. Hartley
Rensselaer Poly. Inst., Troy, N. Y.	F. M. Sebast	W. C. Michels
Rhode Island State Coll., Kingston, R. I.	G. A. Eddy	C. F. Easterbrooks
Rose Poly. Inst., Terre Haute, Ind.	D. L. Fenner	W.F.A. Hammerling
Rutgers Univ., New Brunswick, N. J.	E. C. Siddons	W. H. Bohlke
Santa Clara, Univ.of, Santa Clara, Calif.	Lloyd Whitwam	W. P. Fisher
South Dakota State School of Mines, Rapid City, S. D.	D. A. White	Harold Eade
South Dakota, University of, Vermillion, S. D.	Stanley Boegler	L. E. Crowell
Southern California, Univ. of, Los Angeles, Calif.	Gilbert Dunstan	Osborne Hatch
Stanford Univ., Stanford Univ., Calif.	A. V. Pering	J. G. Sharp
Stevens Inst. of Tech., Hoboken, N. J.	D. B. Wesstrom	G. E. Witham
Swarthmore Coll., Swarthmore, Pa.	T. C. Lightfoot	W. F. Denkhaus
Syracuse Univ., Syracuse, N. Y.	G. F. Kern	T. P. Hall
Tennessee, Univ. of, Knoxville, Tenn.	F. N. Green	B. M. Gallaher
Texas A. & M. Coll. of, College Station, Texas	C. A. Altenbern	J. L. Pratt
Texas, University of, Austin, Tex.	A. L. Mayfield	G. E. Schade
Utah, Univ. of, Salt Lake City, Utah	J. I. Farrell	M. L. Hoag
Virginia Military Inst., Lexington, Va.	R. P. Williamson	M. L. Waring
Virginia Poly. Inst., Blacksburg, Va.	R. M. Hutcheson	M. B. Cogbill
Virginia, Univ. of, University, Va.	R. C. Small	H. M. Roth
Washington, State Coll. of, Pullman, Wash.	Earl Munson	C. E. Peterson
Washington Univ. of, St. Louis, Mo.	R. L. Belshe	J. G. Mazanec, Jr.
Washington, Univ. of, Seattle, Wash.	C. M. Murray, Jr.	Roy H. Crosby
Washington and Lee Univ., Lexington, Va.	R. E. Kepler	Bernard Yoepp
West Virginia Univ., Morgantown, W. Va.	I. L. Smith	P. E. Davis
Wisconsin, Univ. of, Madison, Wis.	John Sargent	Leonard Saari
Worcester Poly.Inst., Worcester, Mass.	D. A. Calder	C. H. Kauke
Wyoming, Univ. of, Laramie, Wyo.	John Hicks	Edward Joslin
Yale University, New Haven, Conn.	W. W. Parker	J. W. Hickley
